The electric grid and the transportation system are the two largest sectors that produce greenhouse gas emissions. When large numbers of vehicles are electrified and draw power from the electric grid, it is important to aim for reduced overall greenhouse gas emissions rather than just shifting emissions from tailpipes to power plant stacks. Controlling the charging of plug-in vehicles to alleviate the impact to the grid has been studied, including the idea of using plug-in vehicles as ancillary services to the grid, possibly with significant renewable power sources connected to the grid. Modeling and simulating this integrated system require information on detailed grid load profiles, power generation pricing and carbon emissions, wind statistics, and vehicle usage statistics. In addition, charging control must balance multiple factors: grid stability, fully charging all vehicles, minimizing data collection and communication, and overall system carbon emission minimization.

Intelligent Transportation Systems

X-EVs, as well as conventional vehicles, will benefit from the ability to analyze traffic and geographical information in real time to quantify the effects of infrastructure, environment, and traffic flow on vehicle fuel economy and emissions, and to permit the application of forecasting and optimization methods for energy management (Gong et al. 2011; Wollaeger et al. 2012). There are significant opportunities to achieve significant fuel savings and emissions reduction by considering the large-scale interactions of vehicles with one another and with the infrastructure, further exploiting the flexibility inherent in X-EVs.

Programmable Logic Controllers

Georg Frey
Saarland University, Saarbrücken, Germany

Synonyms

PLC

Abstract

Programmable logic controllers (PLCs) are a special form of computing hardware and software tailored for use in industrial control. The hardware is built for rough environments and offers various input and output ports for industrial sensor and actuator signals as well as communication systems. The main software features are hard real-time capabilities and a set of standardized programming languages specifically designed for the realization of automation functions.

Keywords

Function blocks; Ladder diagram; Ladder logic; Logic control; Real-time control

Introduction

Since the 1970s, the programmable logic controller (PLC) has been the primary workhorse of industrial automation. For a long time, it has provided a distinct field of research, development, and application, mainly for control engineering. This area has produced its own design methods and programming languages. Due to its importance for industrial application, a lot of these methods have been standardized by the International Electrotechnical Commission (IEC). Currently the most influential standards are IEC 61131 (John and Tiegelkamp 2010) and IEC 61499 (Vyatkin 2011). While the latter one is dedicated to distributed systems, IEC 61131 covers the PLC as such. This standard consists of several parts. The most important ones are:

Part 1 : General information. This part covers the *CONCEPT* of PLCs. It describes the general idea and typical functionalities, most importantly, the cyclic processing of the application program working on a stored image of the input and output values.

Part 2 : Equipment requirements and tests. Here requirements on the PLC *HARDWARE* (electrical, mechanical, and functional) and corresponding tests are defined.

Part 3 : Programming languages. This is the most important part of the standard. Based on already existing PLC programming languages, a harmonization of the *SOFTWARE* structure was achieved. This includes a general software model together with a set of different standardized programming languages. IEC 61131-3 paved the way from proprietary programming solutions to a set of well-accepted languages, allowing easier training of PLC programmers and – to some extent – the reuse of application solutions on different hardware platforms.

While Part 2 is of importance for PLC manufacturers only, Parts 1 and 3 contain relevant information for PLC users, especially for designers of PLC control applications. Before discussing these points, the definition of PLC from IEC 61131-1 is reproduced and discussed:

> A PLC is a digital electrical system used in manufacturing. It utilizes programmable memory to store practice-oriented control programs. Thus is suitable for implementation of specific functions such as combinatorial control, sequence control, time-, count- and arithmetic functions. Due to its special arrangement of digital or analog input/output, it is used for controlling various machines and processes. (. . .)

This definition is focused on the usage of the device and would – taken out of the context – also cover industrial PCs or microcontroller-based control solutions. The specifics of PLC hardware

P

are discussed in Part 2 of the standard. However, much more important for distinguishing a PLC from other control hardware are the properties of the execution model described in Part 2 and discussed in the following.

Execution Model

In designing PLC applications, the execution model has to be considered. The main idea is the cyclic execution together with an I/O image. While microcontrollers and PCs typically use an event-based execution model (the application waits for external events from the environment – interrupts – and reacts accordingly), the PLC follows a time-based scheme (the application scans the environment at instances in time – often a fixed cycle time – and reacts on the new status of the input ports).
A PLC cycle consists of three iterated steps: input reading, program execution, and output writing. Together with the concept of the process image – a reserved memory space where input and output variables are stored – this execution model leads to the following:

(a) During one cycle, input and output values are kept fixed, i.e., a change in input signal values during a cycle will not be seen by the program executed. This means that a temporal change in an input signal value that is shorter than the cycle time may not be registered by the PLC at all.

(b) Changes in output signal settings by the program will be switched to the actual output ports only after execution of the complete program. This actually means that for an output signal where the value is changed several times during one program execution, only the last change will be set to the hardware output of the PLC.

(c) The response time of a PLC, i.e., the time between a change in an input signal and the corresponding reaction at the output port of a PLC, lies between one and two PLC cycles, depending on when the change at the input port occurs relative to the PLC cycle.

While the time needed for input reading and output writing is constant over all cycles, the time for program execution may vary due to conditional execution of some program parts. However, normally the PLC is operated with a fixed cycle time set high enough to allow for the worst-case execution time of the application program.

The advantage of the described concept is the deterministic behavior of the resulting system with a very simple way to determine the timing behavior. This is important for most PLC applications:

(a) Open-loop control, where the reaction to a change of an input signal has to be reached in a limited time, especially in safety-critical applications.

(b) Closed-loop control, where the design of a discrete-time control algorithm is based on the assumption of a fixed sample-time.

To realize control functions, an application program has to be written for the PLC. To this end, Part 3 of the IEC 61131 defines a software model together with a set of programming languages.

Software Model and Programming

The original idea that led to the development of the first programmable logic controller (PLC) in 1968 was to replace hardwired control equipment at machines. Back then, the controllers of machines, for example, lathes or grinders, typically consisted of a cabinet of interconnected relays. The size of such a controller could be considerable and its failure rate was high due to mechanical defects of single relays. Furthermore, the initial setup was very time-consuming and error prone, because the relays (often hundreds of them) had to be wired by hand. The biggest

drawback of this technology, however, was the problems arising if a controller had to be changed, employing a new function or adjusting to a new production task. Then the hardwired structure had at least partially to be disassembled and rewired. Here was the main advantage of a controller that could be adjusted by changing software instead of hardware.

Since the first PLCs in the early seventies reached the market, graphical programming methods are used to develop the control algorithms. These are ladder diagram (LD, sometimes also referred to as ladder logic) and later function block diagram (FBD). The implementation of LD on the very first PLC (the Modicon 084) was intended to allow an easy access for the people doing hardwired relay logic until then. (More on the history of PLCs can be found on the website of Dick Morley, commonly known as the father of the PLC (http://www.barn.org/FILES/historyofplc.html).)

LD, at least in its early forms, is basically the graphical representation of its hardwired forefather. The name ladder comes from the fact that on both sides of the drawing, there is a power rail and horizontally between those rails, like rungs on a ladder, sequences of logical element are drawn. The basic of these elements are relays (switches), depending on input signals or internal variables, and coils (memories to store variables and set output signals). The ladder is processed in a top-down and left-right fashion.

Figure 1 shows an example of an LD. Every rung can be read as an IF THEN ELSE statement. The first rung of the ladder means IF (Var1 $= 1$ AND Var2 $= 1$) THEN (Var3 $:= 1$; Var4 $:= 0$) ELSE (Var3 $:= 0$; Var4 $:= 1$). The second rung is IF (Var3 $= 1$ OR Var4 $= 0$) THEN (Var1 $:= 1$) ELSE (Var1 $:= 0$).

While LD resembles relay logic, FBD is a graphical mimicking of the wiring of simple logic gates, like AND, OR, NOT, or FLIP-FLOP. Both languages (LD as well as FBD) are still part of the IEC 61131-3. However, they are not well suited for the description of sequential and concurrent algorithms because they have no means
Programmable Logic Controllers, Fig. 1 Example of a PLC program written in Ladder Diagram (LD)

for the visual description of the control flow in a program.

The IEC 61131-3 standard also contains a language that is intended for the graphical description of sequential and concurrent behavior: the sequential function chart (SFC). The SFC is based on Grafcet (David 1995) and represents a form of Petri net (with very special dynamics and functionality). Due to its high functionality, SFC can be easily applied for the structuring of a PLC program on a high level. However, it is cumbersome (and by the standard also not intended) to use for the specification of a low-level sequential algorithm, as, for example, the alternative switching between two motors.

In addition to the three graphical languages, there are also two textual languages in the standard: the assembler-like Instruction List (IL) and the Pascal-like Structured Text (ST).

The decision for one of the languages is based on functional aspects of the application to be realized (high-level languages SFC and ST vs. low-level languages LD, IL, and FBD) but also on traditions in the application domain (e.g., LD in automotive manufacturing vs. FBD in process industry), the geographical region (e.g., LD in the US vs. IL in Germany), and the preferences of the programmer (graphical vs. textual). To allow for flexible solutions and the optimal choice of languages, IEC 61131-3 allows the use of different languages for different parts of the control application.

An application in IEC 61131-3 is structured into program organization units (POUs). Each of the POUs contains a header in a unified syntax for parameter and variable definitions and a body for

P

the actual program code. This body can be written in any one of the defined PLC languages.

There are three types of POUs: Program, Function Block, and Function. A program is the top-level POU of a PLC application. Only in a program, variables can be linked to actual input and output ports. A program can call Function Blocks which in turn may call other function blocks. Programs and function blocks can also call Functions. A POU of type function has no internal memory while a Function Block has memory.

IEC 61131-3 introduced the type and instance concept into PLC programming. A Function Block is always the instantiation of a Function Block Type. Each instantiation gets its own name and variable space. This concept is similar to – but much older than – the class-object instantiation idea of object-oriented programming languages. The exclusive use of symbolic variables without direct references to hardware addresses or ports in Function Blocks allows their easy reuse in one or more applications and the definition of widely applicable Function Block (Type) Libraries.

Summary and Future Directions

PLCs are a proven technology in industrial automation. They follow a simple but deterministic execution and software model. This is the main reason why PLCs are still here and will be here for quite some time to come even if there is faster and fancier technology like embedded PCs available.

Currently the third edition of IEC 61131-3 is nearly ready for publishing. In addition to minor corrections, this new edition adds some concepts from object-oriented programming to the existing software model. First tools on the market already support these extensions.

For the future, two trends can be seen. First, there is a growing trend to integrate PLC programming into model-based software development processes: either by generating PLC code from existing model-based toolchains or by integrating model-based approaches, especially from

the object-oriented domain, into PLC programming environments. Either way this is due to the fact that the complexity in PLC application is rising while the development time should be decreased.

Second, there is a growing interest in the use of formal methods in the PLC domain. In recent years, a lot of interdisciplinary work was aimed in this direction. This work results in the formalization of different steps in the control design process depending on what problems are to be solved (Frey and Litz 2000):

1. The demand for reduced development time and the possible reuse of existing software modules result in the need for a formal approach to the development of the PLC programs.
2. The demand for high-quality solutions and especially the application of PLC in safety-critical processes result in the need for validation procedures, i.e., formal methods to prove specific static and dynamic properties of the programs.
3. The large numbers of already installed PLC programs, together with the high expense of programming, lead to the search for verification and validation methods that can be applied directly to programs written in PLC-specific programming languages such as ladder diagram.

To conclude, more than 50 years after its invention, the PLC is still an industrial success story, and due to ever-increasing demands on the complexity and correctness of its applications, it also still provides much room for further research and development.

Pursuit-Evasion Games and Zero-Sum Two-Person Differential Games

Pierre Bernhard
INRIA-Sophia Antipolis Méditerranée, Sophia Antipolis, France

Abstract

Differential games arose from the investigation, by Rufus Isaacs in the 1950s, of pursuit-evasion problems. In these problems, *closed-loop strategies* are of the essence, although defining what is exactly meant by this phrase, and what is the "Value" of a differential game, is difficult. For closed-loop strategies, there is no such thing as a "two-sided maximum principle," and one must resort to the analysis of Isaacs' equation, a Hamilton Jacobi equation. The concept of viscosity solutions of Hamilton-Jacobi equations has helped solve several of these issues.

Keywords

Historical Perspective

The history of differential games (DG in short) starts with Rufus Isaacs, who coined the phrase in his pioneering work of the early 1950s (Isaacs 1951), which was largely ignored until the publication of his book Isaacs (1965). Through the investigation of particular problems, Isaacs invented by himself (with his own names) the concepts of state and control variables, of feedback, his "tenet of transition" – better known as Bellman's optimality principle – the (Hamilton-Jacobi-Caratheodory-)Isaacs equation, barriers, some difficult corner conditions ("equivocal lines"), singular arcs ("universal lines"), etc.

Another very early work was Kelendzerize's chapter "A Pursuit Problem" in the historical book by Pontryagin et al. (1962), but it lacked closed-loop strategies.

John Breakwell and a few followers (Breakwell and Merz 1969; Breakwell 1977) picked up Isaacs' work where he had left it, still working on particular problems, but adding the power of the computer to analyze the solution of Isaacs' equation via the structure and singularities of fields of extremal trajectories, while most of the literature concentrated on making precise the concepts of closed-loop strategies and of the Value of the game. Prominent figures in that quest are Krasovskii and Subbotin (1977), Fleming (1961), Friedman (1971), Blaquière et al. (1969), Elliot and Kalton (1972), Emilio and Roxin (1969), and Varaiya and Lin (1969) who together invented the concept of non-anticipative strategies.

The major later innovation was Crandall and Lions' viscosity solutions of PDEs (Crandal and Lions 1983; Lions 1982) applied to DGs and its Isaacs equation by Evans and Souganidis (1984) and Lions and Souganidis (1985).

We also refer the reader to the entry (Quincampoix 2009) of another Springer Encyclopedia.

General Setup

We shall be interested in (continuous time) two-person zero-sum DGs with complete information, this last phrase meaning that both players know exactly and instantly the state of the system, but (usually) not their opponent's control.

The available space of a short article does not allow us to attempt to give the most general setup of a zero-sum two-person perfect-information differential game. We shall therefore concentrate on a typical class, with a finite dimensional state space, as follows. The data are:

1. A two-player dynamical system with state $x \in \mathbb{R}^n$, control variables $u \in \mathsf{U} \subset \mathbb{R}^\ell$, $v \in \mathsf{V} \subset \mathbb{R}^m$ (U and V will often be assumed compact), and its dynamics

$$\dot{x} = f(t, x, u, v), \qquad x(t_0) = x_0.$$

Denoting $\mathcal{U}$ and $\mathcal{V}$ the sets of measurable functions from $\mathbb{R}$ to U and V respectively, one assumes regularity and growth conditions on f to guarantee existence and uniqueness of the solution $x(\cdot)$ for all (t_0, x_0) and all $(u(\cdot), v(\cdot)) \in \mathcal{U} \times \mathcal{V}$.

2. A termination condition, often given by a target set $\mathcal{T} \in \mathbb{R} \times \mathbb{R}^n$, open or closed according to necessity, defining a final time as $t_1 = \inf\{t \mid (t, x(t)) \in \mathcal{T}\}$. If $\mathcal{T} = \{T\} \times \mathbb{R}^n$, final time is fixed and equal to T. The question of whether there is a finite t_1 is one of central interest in pursuit-evasion games.

3. Sets of admissible closed-loop strategies Φ and Ψ. One should choose them in such a way that replacing (u, v) by a pair $(\phi, \psi) \in \Phi \times \Psi$ in the dynamics always produces a (unique) admissible pair of control functions $(u(\cdot), v(\cdot)) = \Gamma(t_0, x_0; \phi, \psi) \in \mathcal{U} \times \mathcal{V}$.

4. A performance measure, or payoff, typically

$$J(t_0, x_0; u(\cdot), v(\cdot)) = \begin{cases} K(t_1, x(t_1)) + \displaystyle\int_{t_0}^{t_1} L(t, x(t), u(t), v(t))\, \mathrm{d}t & \text{if } t_1 < \infty, \\ \infty & \text{if } t_1 = \infty. \end{cases}$$

We let

$$G(t_0, x_0; \phi, \psi) := J(t_0, x_0; \Gamma(t_0, x_0; \phi, \psi)).$$

5. A concept of "solution," where the first player wants to minimize the performance index while the second one wishes to maximize it. (In our choice of definition of J, we have assumed that player one wants over anything else to make the game terminate. If we define J as the integral even for infinite end-time, Isaacs' tenet of transition may not hold.)

If

$$\inf_{\phi \in \Phi} \sup_{\psi \in \Psi} G(t_0, x_0; \phi, \psi)$$

$$= \sup_{\psi \in \Psi} \inf_{\phi \in \Phi} G(t_0, x_0; \phi, \psi) = V(t_0, x_0),$$

then V is called the Value function of the game. Several concepts of upper Value and lower Value may be defined (including the first and second terms above) that have to coincide for a Value to exist.

Isaacs' Condition In the framework of this short entry, we shall always assume that the game satisfies *Isaacs' condition*. It bears on the *Hamiltonian* $H(t, x, p, u, v) := L(t, x, u, v) + \langle p, f(t, x, u, v) \rangle$ and reads

$$\forall (t, x, p) \in \mathbb{R} \times \mathbb{R}^n \times \mathbb{R}^n,$$

$$\inf_{u \in \mathsf{U}} \sup_{v \in \mathsf{V}} H(t, x, p, u, v)$$

$$= \sup_{v \in \mathsf{V}} \inf_{u \in \mathsf{U}} H(t, x, p, u, v). \tag{1}$$

Strategies and Value

In pursuit-evasion games, the concept of closed-loop strategies is of the essence, and it is extremely important for all DGs. Yet, allowing state

feedback strategies such as $u(t) = \phi(t, x(t))$, $v(t) = \psi(t, x(t))$, poses a difficult problem: what classes Φ and Ψ of functions ϕ and ψ to allow? The notations $\inf_\phi$ or $\sup_\psi$ have no meaning if one does not answer that question. Experience tells us that discontinuous feedbacks are necessary to find the solution of many examples, but then existence, or uniqueness, of the solution of the dynamical equation cannot be guaranteed.

Isaacs' K-strategies were a partial attempt to address this issue. More developed concepts were proposed, from limit of piecewise constant, or piecewise open-loop, controls (Fleming 1961; Friedman 1971) to extensions of the notion of solution of a differential equation (Krasovskii and Subbotin 1977), also proving the existence of a Value. The equivalence of all these Values was an issue until the advent of viscosity solutions of Isaacs' equation.

A tool used to accommodate state-feedback strategies (Bernhard 1977) is

Lemma 1 (Berkovitz) *If $\mathcal{V} \subset \Psi$, then, $\forall \phi$ for which this expression is well defined,*

$$\sup_{\psi \in \Psi} G(t_0, x_0; \phi, \psi) = \sup_{v(\cdot) \in \mathcal{V}} G(x_0, t_0, \phi, v(\cdot)).$$

As a consequence, a saddle-point $(\phi^\star, \psi^\star)$ solution is defined by

$$\forall u(\cdot) \in \mathcal{U}, \forall v(\cdot) \in \mathcal{V}$$
$$G(t_0, x_0; \phi^\star, v(\cdot)) \leq V(t_0, x_0)$$
$$\leq G(t_0, x_0; u(\cdot), \psi^\star), \qquad (2)$$

confronting the closed-loop saddle point strategies to open-loop controls only. (This proves useful in the analysis of Nash equilibria of nonzero-sum DGs.)

Another consequence of Berkovitz' lemma is that if a DG has a saddle point in open-loop controls, it is a saddle point over closed-loop controls as well. (But the existence condition may be less stringent for the later.) The relationship between different forms of the strategies has been

further clarified by Başar (1977) and Başar and Olsder (1982).

As far as the existence of the Value is concerned, the problem for a large class of DGs is solved with *non-anticipative strategies* defined as $\Phi : \mathcal{V} \to \mathcal{U}$ such that

$$\forall t, \ [\forall s < t \quad v_1(s) = v_2(s)] \Rightarrow [\phi(v_1(\cdot))(t)$$
$$= \phi(v_2(\cdot))(t)],$$

and likewise for Ψ (notice that for this concept of strategies, (2) is the natural formulation of a saddle point) and with the notion of *viscosity solution of Isaacs' equation*. See Theorem 1 below.

Games of Pursuit Evasion

An important class of DGs is the game of pursuit evasion. Typically, in these games the state x is composed of a sub-vector y of *Pursuer state(s)* and a sub-vector z of *Evader state(s)*. The dynamical function f is separated likewise, the dynamics of the Pursuer depending on the *Pursuer's control(s)* and that of the Evader on the *Evader's control(s)*. Typically, the payoff is time until *capture* defined as $(t, x(t)) \in \mathcal{T}$ (the target is often called *capture set*). This form of DG automatically satisfies Isaacs' condition (1).

Qualitative Game
In pursuit-evasion games, the main issue is to distinguish initial states, called *capturable*, for which a Pursuer's strategy causing finite-time capture against any defense exists, from those, called *safe*, for which the Evader has a strategy guaranteeing *escape* against any defense. This is the topic of the *qualitative game* or *game of kind* (Isaacs). A *theorem of the alternative* is one which states that for a particular (class of) game(s), every initial state is either capturable or safe. Such theorems have been proved for classes of pursuit-evasion games covering essentially all cases of interest, under Isaacs condition (1) with $L = 0$ (Cardaliaguet 1996; Cardaliaguet et al. 2001; Krasovskii and Subbotin 1977).

Capturable states are separated from safe states by a *barrier*, a piecewise smooth manifold which has to be *semipermeable*. This means that for all (t, x) on the barrier where this barrier is a smooth manifold with normal $v(t, x)$, it should hold that

$$\min_{u \in U} \max_{v \in V} \langle v(t, x), f(t, x, u, v) \rangle$$
$$= \max_{v \in V} \min_{u \in U} \langle v(t, x), f(t, x, u, v) \rangle = 0 \, .$$

A minimax pair $(u, v) = (\hat{\varphi}(t, x, v), \hat{\psi}(t, x, v))$ is called a pair of semipermeable strategies. If the boundary of the capture set is a smooth manifold with local outward normal $n(t, x)$, its *usable part* is the region where $\inf_{u \in U} \sup_{v \in V} \langle n(t, x), f(t, x, u, v) \rangle < 0$. The *natural barrier* is a semipermeable manifold constructed backward from its boundary (the BUP), with n as final v and using the characteristic equations:

$$\dot{x} = f(x, \hat{\phi}, \hat{\psi}) \, , \qquad \dot{v}^t = -v^t \frac{\partial f(t, x, \hat{\varphi}, \hat{\psi})}{\partial x} \, .$$

(These trajectories are *abnormal trajectories* of the calculus of variations). In most examples, only part of the manifold thus constructed is a barrier, and the complete barrier is made of manifolds pieced together according to a junction condition insuring that the corners "do not leak" (Breakwell), analogous to the corner conditions of the next section.

Quantitative Game

The quantitative game, or *game of degree* (Isaacs), is played inside the capture zone, typically with time of capture as the payoff. It is ruled by Isaacs' equation in a fashion similar to that of games of finite duration (see below). Yet, the interplay between the qualitative and the quantitative game may be quite subtle and plays a prominent role in determining the actual capture zone. The Value function is usually discontinuous across other barriers inside the capture zone.

Other Approaches

Other approaches have been developed to solve games of pursuit evasion.

An early approach by Pontryagin (1967), extended by Pshenichnyi (1968), used geometric methods for linear pursuit-evasion games with convex compact control sets. Krasovskii's *stable bridges* (Krasovskii and Subbotin 1977) are a concept close to Isaacs' semipermeability. Patsko and Turova (2001) have developed, for some families of DGs, an efficient numerical procedure to compute recursively hypersurfaces of constant time-to-capture, whose discontinuities display the barriers. Cardaliaguet et al. (1999) have developed a theoretical and numerical procedure building on Aubin's viability theory, which requires less regularity on the data than other approaches.

Provided that care be applied, a quantitative game may be transformed into a family of qualitative games – an approach used by Krasovskii, Blaquière et al., and Cardaliaguet et al. – and conversely, a fruitful approach is to investigate capturability of initial states as a function of a parameter defining the "size" of the capture set, imbedding the qualitative game into a quantitative game of the type *game of approach*.

Games of Finite Duration

Wherever termination of the game is not an issue, the major tool in investigating a DG is Isaacs' equation, a partial differential equation bearing on the Value function:

$$\forall (t, x) \notin \mathcal{T} \, , \quad \frac{\partial V}{\partial t}(t, x)$$
$$+ \min_{u \in U} \max_{v \in V} H(t, x, \nabla_x V, u, v) = 0 \, ,$$
$$\forall (t, x) \in \mathcal{T} \, , \quad V(t, x) = K(t, x) \, .$$
$$(3)$$

For any DG where all trajectories are transverse to the boundary $\partial \mathcal{T}$, and with adequate regularity conditions on the data (and still under condition (1)), it holds that

Theorem 1 *The DG has a Value in non-anticipative strategies, which is the only bounded,*

uniformly continuous viscosity solution of the equation obtained by changing signs in (3) as $-\partial V/\partial t - \min_{u \in \cup} \max_{v \in V} H = 0$. *And all other Values coincide.*

One possible way to solve Isaacs' equation is via the investigation of its field of characteristics. Their equations are Isaacs' *retrograde path equations*: let $(\hat{u}, \hat{v}) = (\hat{\varphi}(t, x, p), \hat{\psi}(t, x, p))$ be the saddle point of $H(t, x, p, u, v)$, assumed here to be unique, one integrates from the target set backward:

$$\dot{x} = f(t, x, \hat{u}, \hat{v}), \tag{4}$$

$$\dot{p} = -\left(\frac{\partial H(t, x, p, \hat{u}, \hat{v})}{\partial x} \right)^t. \tag{5}$$

The above equations are similar to Pontryagin's maximum principle equations. However, a major difference lies in the *corner conditions*. While Pontryagin's theorem extends to control theory the Erdman-Weierstrass condition stating that the adjoint vector (here p) is continuous along an extremal trajectory, in (4) and (5), p is to coincide with $\nabla_x V$ and **may be discontinuous along an extremal trajectory**. These discontinuities cannot be found by a local analysis along an isolated trajectory and require that a complete field of extremals be constructed, synthesizing a state feedback strategy.

The analysis of the conditions that hold at such corners, equivocal manifolds (Isaacs), envelope manifolds (Breakwell), and focal manifolds (Merz), has been a large part of the early Isaacs-Breakwell theory. It has been for its larger part synthesized by Bernhard (1977), except a general constructive analysis of focal manifolds which had to wait until Melikyan and Bernhard (2005).

The absence of a "two-sided Pontryagin principle" for closed-loop differential games forces one to resort to the solution of Isaacs' equation or an equivalent. This is the reason why no practical method of solution exists beyond a state dimension of 3 or 4, counting time if the game is not time invariant. An exception is the linear quadratic game. (See article ▶ Linear Quadratic Zero-sum Two-person Differential Games in this encyclopaedia).

Conclusion

Except for very particular games, "solving" a DG remains a difficult task. Numerical methods suffer the famous "curse of dimensionality." Moreover, many of them strive to compute the Value function. But the optimal strategies typically depend on the gradient of the Value function, requiring a stronger convergence of the approximation algorithms than pointwise, or C^0 or L^2, if they are to be computed as well. Further advances in numerical algorithms tackling this problem would be useful, as well as uncovering new classes of DGs for which further analytical results could be obtained.

QFT

Abstract

Designing reliable and high-performance control systems is an essential priority of every control engineering project. In many practical circumstances the presence of model uncertainty challenges the design. One robust control approach for these cases, deeply rooted in the classical frequency domain, is quantitative feedback theory (QFT). Providing a control solution that guarantees the achievement of a multi-objective set of performance specifications for every plant within the model uncertainty (quantification), QFT balances the trade-off between the simplicity of the compensator

structure and the minimization of the activity of the controller at each frequency ("cost of feedback"). Previous results indicate that the QFT methodology has been able to provide successful control solutions to a large variety of real applications, including linear and non-linear plants, stable and unstable systems, multi-input multi-output processes, minimum and non-minimum phase plants, containing time-delay, lumped or distributed parameters, etc.

Keywords

Frequency domain control; Quantitative controller design; Robust control

Definition

Quantitative Feedback Theory (QFT) is a robust control engineering design methodology that uses the feedback to simultaneously and quantitatively: (1) reduce the effects of *plant uncertainty* and (2) satisfy *performance control specifications*. The method searches for a controller that guarantees the satisfaction of the required performance specifications for every plant within the model uncertainty (*robust control*).

QFT is rooted in the classical frequency domain. It involves Bode diagrams and Nichols charts (magnitude/phase diagrams). It relies on the observation that feedback is needed when

the plant presents model uncertainty and/or there are uncertain disturbances. QFT balances quantitatively: (a) the simplicity of the controller structure, (b) the minimization of the so-called *cost of feedback*, controller magnitude at each frequency, (c) the plant model uncertainty and (d) the achievement of the desired performance specifications, all at each frequency of interest. The technique has been successfully applied to a wide variety of real-world control problems.

Historical Notes

Many of the frequency domain fundamentals were established by Hendrik Bode in his seminal book *Network Analysis and Feedback Amplifier Design*, published in 1945 (Van Nostrand). The book strongly influenced the understanding of automatic control theory for many years, especially where system sensitivity and feedback constraints are concerned.

Almost 20 years later, in 1963, a new influential book entitled *Synthesis of Feedback Systems* (Academic Press), written by Isaac Horowitz, proposed for the first time a formal combination of the frequency domain methodology with plant model uncertainty (*robust control*) under a quantitative analysis. The new book addressed an extensive set of sensitivity problems in feedback control and was the first work in which a control problem was treated quantitatively in a systematic way. The book laid the foundation

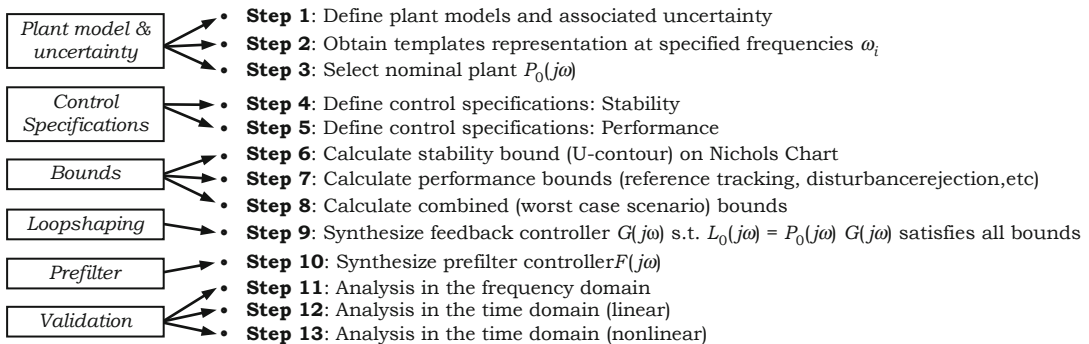
for a new control design methodology that had been introduced briefly in a previous paper by Horowitz in 1959: the one that became known as *Quantitative feedback theory* (or QFT) in the early 1970s.

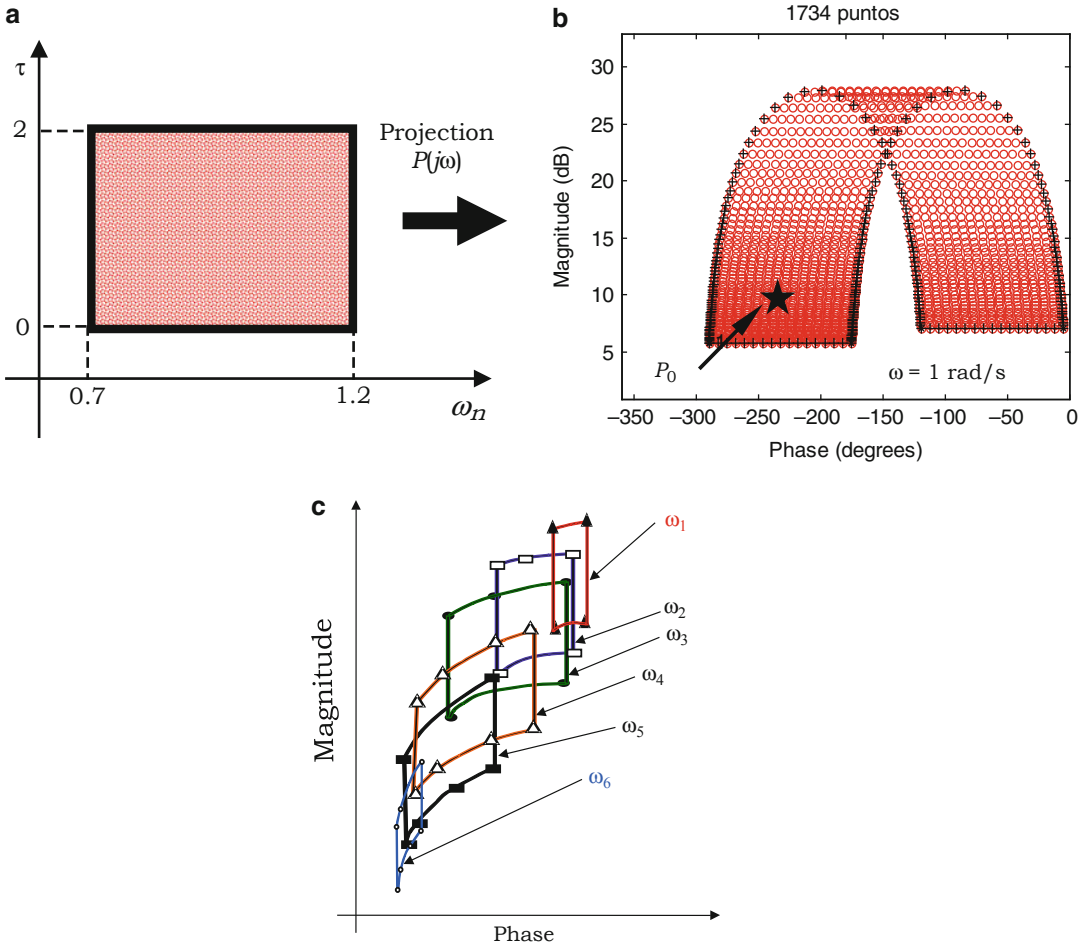
Fundamentals

A detailed study of the *QFT fundamentals and applications* can be found in the books written by Garcia-Sanz and Houpis (2012), Houpis et al. (2006), Sidi (2002), Yaniv (1999), and Horowitz (1993); see the "Recommended Reading" section.

The QFT methodology provides a multi-criteria engineering understanding of the controller design process, as it quantifies the balance among the controller structure, cost of feedback, performance specifications, and model plant uncertainty at each frequency of interest. The basic steps of the QFT methodology are summarized in Fig. 1 and are presented in the following sub-sections.

Define Plant Model and Uncertainty: Templates Generation (Steps 1, 2 & 3)

First of all, the dynamics of the plant to be controlled are described in the frequency domain. Taking the plant model in terms of transfer functions with mixed parametric, non-parametric and even model structure uncertainty, the frequency domain description is carried out


Quantitative Feedback Theory, Fig. 1 Summary of QFT controller design methodology


Quantitative Feedback Theory, Fig. 2 From the *parameter space* to the *Nichols chart*: (**a**) 2-dimensional parameter space, (**b**) Template of the plant $P(j\omega)$ at $\omega = 1$ rad/s, (**c**) Typical templates for frequencies $\omega \in [\omega_{\min}, \omega_{\max}]$

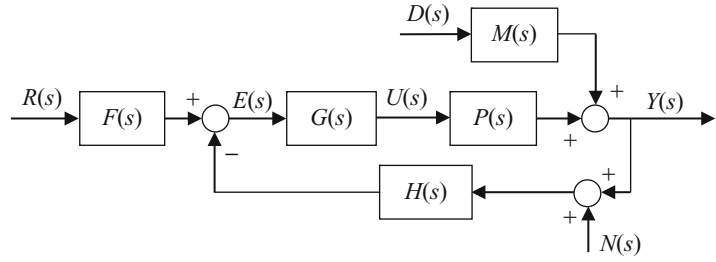
by calculating "*templates*", which are sets of complex numbers at each frequency of interest $\omega \in [\omega_{\min}, \omega_{\max}]$ rad/second: a projection of the n-dimensional parameter space through the transfer function/functions onto the Nichols chart.

As an example, and for "$\omega = 1$ rad/s, Fig. 2b represents the QFT template of the 3-parameter plant $P(j\omega) = exp(-j\omega\,\tau)\Big/ \Big((j\omega)^2 + 2\,\zeta\,\omega_n\,(j\omega) + \omega_n^2\Big)$, with $\omega_n \in [0.7, 1.2]$, $\tau \in [0, 2]$, and $\zeta = 0.02$.

Each template $\Im P(j\omega_i) = \{P(j\omega_i)\}$ represents on the Nichols chart and at a specific frequency ω_i all the possible plants within the model uncertainty (see Fig. 2c). One particular case, defined as a set of specific parameters of the n-dimensional parameter space is arbitrarily selected to define the nominal plant $P_0(j\omega)$, a member of the family of plants within the uncertainty (see Fig. 2b).

Define Control Specifications (Steps 4 & 5)

The standard two-degree-of-freedom (2DOF) control system diagram is shown in Fig. 3.

Quantitative Feedback Theory, Fig. 3 Multi-Input-Single-Output 2DOF feedback control system. $s \sim j\omega$


It includes the set of uncertain plants $P(j\omega)$ to be controlled, the disturbance dynamics $M(j\omega)$, the feedback path dynamics $H(j\omega)$, and the loop controller $G(j\omega)$ and prefilter $F(j\omega)$, both to be design. On the other hand, $R(j\omega)$, $E(j\omega)$, $U(j\omega)$, $Y(j\omega)$, $D(j\omega)$, and $N(j\omega)$ are vectors representing respectively the reference input, signal error, controller output, plant output, disturbance input, and sensor noise input. From the diagram (Fig. 3), it is easy to derive the following three input/output equations (note the dependency on $j\omega$ is removed):

$$Y = \frac{PG}{1+PGH}FR + \frac{M}{1+PGH}D - \frac{PGH}{1+PGH}N;$$

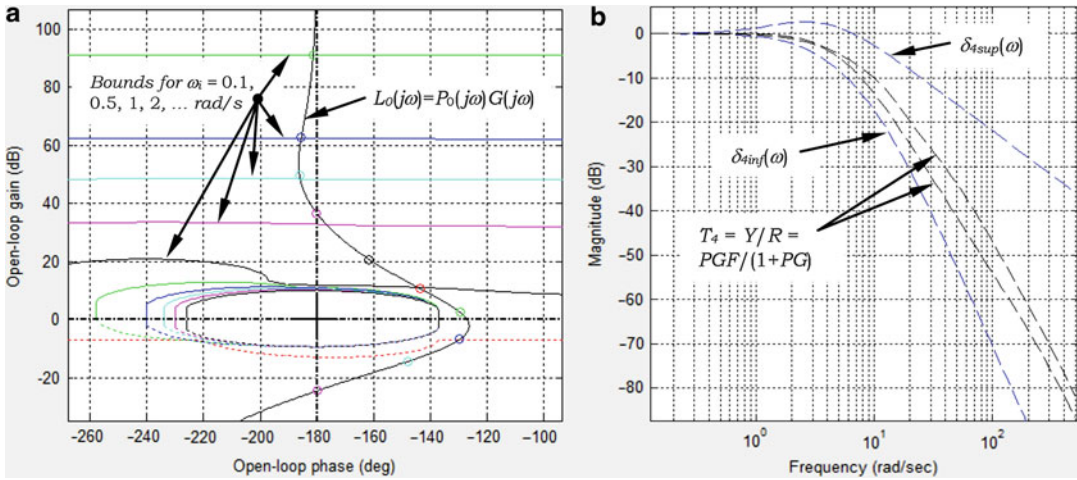
$$U = \frac{G}{1+PGH}FR - \frac{GH}{1+PGH}(MD+N) \text{ and}$$

$$E = \frac{1}{1+PGH}FR - \frac{HM}{1+PGH}D - \frac{H}{1+PGH}N$$

Without losing generality, and with a straightforward block diagram manipulation, $F(s)$ and $G(s)$ can be modified to have $H(s) = 1$. Now, the stability and performance specifications are defined by limiting the magnitude of each transfer function of the three previous equations at each frequency of interest, $|T_k(j\omega)| \leq \delta_k(\omega)$, $k = 1$–4, such that,

Stability and noise reduction: $|T_1(j\omega)| =$
$$\left|\frac{Y(j\omega)}{R(j\omega)\,F(j\omega)}\right| = \left|\frac{Y(j\omega)}{N(j\omega)}\right| = \left|\frac{P(j\omega)\,G(j\omega)}{1+P(j\omega)\,G(j\omega)}\right|$$
$\leq \delta_1(\omega), \quad \omega \in \Omega_1,$

Disturbance rejection: $|T_2(j\omega)| = \left|\frac{Y(j\omega)}{D(j\omega)}\right| =$
$$\left|\frac{M(j\omega)}{1+P(j\omega)\,G(j\omega)}\right| \leq \delta_2(\omega), \quad \omega \in \Omega_2,$$

Control effort reduction: $|T_3(j\omega)| =$
$$\left|\frac{U(j\omega)}{M(j\omega)\,D(j\omega)}\right| = \left|\frac{U(j\omega)}{N(j\omega)}\right| = \left|\frac{U(j\omega)}{R(j\omega)\,F(j\omega)}\right| =$$
$$\left|\frac{G(j\omega)}{1+P(j\omega)\,G(j\omega)}\right| \leq \delta_3(\omega), \quad \omega \in \Omega_3$$


Reference tracking: $\delta_{4\text{inf}}(\omega) < |T_4(j\omega)| =$
$$\left|\frac{Y(j\omega)}{R(j\omega)}\right| = \left|F(j\omega)\,\frac{P(j\omega)\,G(j\omega)}{1+P(j\omega)\,G(j\omega)}\right| \leq$$
$\delta_{4\text{sup}}(\omega), \quad \omega \in \Omega_4,$

$$\frac{|G(j\omega)\,P_d(j\omega)|}{|G(j\omega)\,P_e(j\omega)|}\,\frac{|1+G(j\omega)\,P_e(j\omega)|}{|1+G(j\omega)\,P_d(j\omega)|} \leq \delta_4(\omega)$$
$$= \frac{\delta_{4\sup}(\omega)}{\delta_{4\inf}(\omega)}, \quad \omega \in \Omega_4$$

QFT Bounds (Steps 6, 7 & 8)

For the nominal plant $P_0(j\omega)$, the QFT methodology converts the stability and performance specifications $\delta_k(\omega)$ and the model plant uncertainty into a set of constrains or bounds for each frequency of interest on the Nichols chart (the *Horowitz-Sidi Bounds*).

The ω_i plant template, $\Im P(j\omega_i) = \{P(j\omega_i)\}$, is approximated by a finite set of plants $\{P_r(j\omega_i), r = 1, 2 \ldots\}$. Each plant can be expressed in its polar form as $P_r(j\omega_i) = p(\omega_i)\,exp(j\theta(\omega_i)) = p\angle\theta$. Likewise the controller polar form is $G(j\omega_i) = g(\omega_i)\,exp(j\phi) = g\angle\phi$, with a controller phase ϕ that varies from -2π to 0. Therefore, and for every frequency ω_i, the previous control specifications $\{|T_k(j\omega_i)| \leq \delta_k(\omega_i), k = 1, \ldots, 4\}$ are translated into a set of quadratic inequalities with the format $I_{\omega_i}^k(p, \theta, \delta_k, \phi) = a\,g^2 + b\,g + c \geq 0$, such that,

Quantitative Feedback Theory, Fig. 4 (**a**) QFT-bounds and $G(j\omega)$ design –loopshaping–. (**b**) Prefilter $F(j\omega)$ design: reference tracking specifications $\delta_{4\text{sup}}(\omega)$ and $\delta_{4\text{inf}}(\omega)$, and *upper* and *lower* limits of T_4 due to the plant uncertainty: $\delta_{4\text{inf}}(\omega) \leq |T_4| \leq \delta_{4\text{sup}}(\omega)$

Stability and noise reduction: $p^2 \left(1 - \frac{1}{\delta_1^2}\right)$
$g^2 + 2\,p\,\cos(\phi + \theta)\,g + 1 \geq 0,$

Disturbance rejection: $p^2\,g^2 + 2\,p\,\cos(\phi + \theta)$
$g + \left(1 - \frac{m^2}{\delta_2^2}\right) \geq 0,$ with typically $m = p, 1,$
or other options,

Control effort reduction: $\left(p^2 - \frac{1}{\delta_3^2}\right)\,g^2 +$
$2\,p\,\cos(\phi + \theta)\,g + 1 \geq 0,$ and

Reference tracking: $p_e^2 p_d^2 \left(1 - \frac{1}{\delta_4^2}\right)\,g^2 +$
$2\,p_e\,p_d \left(p_e\,\cos(\phi + \theta_d) - \frac{p_d}{\delta_4^2}\,\cos(\phi + \theta_e)\right) g$
$+ \left(p_e^2 - \frac{p_d^2}{\delta_4^2}\right) \geq 0$

Now, with an appropriate algorithm (see references), the above quadratic inequalities are translated into a set of curves on the Nichols chart for each frequency of interest and type of specification: the *individual specification bounds*. Then, the more demanding (worst case) bound, i.e., the most restrictive one at every phase and each frequency of interest is computed to obtain the intersection of bounds, or the *combined QFT bounds* (see Fig. 4a).

Controller $G(j\omega)$ Design: Loop-Shaping (Step 9)

Although the objective of designing a controller for an infinite number of plants seems to be a very arduous task (there is an infinite number of plants due to the model uncertainty), the integration of all the information (uncertainty and specifications) in a set of simple curves (the QFT bounds) will allow the designer to use just a single plant, the nominal plant P_0, and the bounds to design the controller.

Then, in the design stage (loop-shaping), the controller $G(j\omega)$ is synthesized on the Nichols chart by adding poles and zeros until the nominal loop, defined as $L_0(j\omega) = P_0(j\omega)G(j\omega)$, lies near its bounds (see Fig. 4a). The bounds express the plant models with uncertainty and the performance specifications at each frequency. An optimal controller in the sense of QFT will be obtained if $L_0(j\omega)$ lies exactly on the bounds at each frequency. Practically speaking, a good design will place $L_0(j\omega)$ above the continuous-line bounds and below the dashed-line bounds, and will have the minimum possible magnitude at every frequency. A general formulation for the controller structure $G(s)$ is expressed by the following transfer function:

$$G(s) = \frac{k_G \prod\limits_{i=1}^{n_{rz}} \left(\frac{s}{z_i} + 1\right) \prod\limits_{i=1}^{n_{cz}/2} \left(\frac{s^2}{|z_i|^2} + \frac{2\,Re(z_i)}{|z_i|^2}s + 1\right)}{s^r \prod\limits_{j=1}^{m_{rp}} \left(\frac{s}{p_j} + 1\right) \prod\limits_{j=1}^{m_{cp}/2} \left(\frac{s^2}{|p_j|^2} + \frac{2\,Re(p_j)}{|p_j|^2}s + 1\right)}$$

where k_G is the controller gain, z_i is a zero (real or complex) with m_{rz} and m_{cz} the number of real and complex zeroes respectively, and p_j is a pole (real or complex) with m_{rp} and m_{cp} the number of real and complex poles respectively (m_{cz} and m_{cp} even numbers). The controller may have also some poles at the origin (integrators), with $r = 0$, 1 or 2, etc.

Prefilter $F(j\omega)$ Design (Step 10)

If the feedback system includes a reference tracking problem, then the best choice is to use a prefilter $F(s)$ – the second degree of freedom. While the feedback controller $G(s)$ reduces the effect of the uncertainty and improves stability, disturbance rejection, and other specifications, the prefilter $F(s)$ is designed to fulfill reference tracking requirements. Figure 4b shows a typical prefilter design in the Bode diagram. $\delta_{4\sup}(\omega)$ and $\delta_{4\inf}(\omega)$ are the reference tracking specifications, defined as a band (outer dashed lines, Fig. 4b). The transfer function T_4 shows an upper and a lower limit (inner dashed lines, Fig. 4b) due to the plant uncertainty. After an appropriate prefilter design, the T_4 limits will be in the middle of the $\delta_{4\sup}$–$\delta_{4\inf}$ band:

$$\delta_{4\inf}(\omega) \le |T_4| \le \delta_{4\sup}(\omega), |T_4(j\omega)| = \left|\frac{Y(j\omega)}{R(j\omega)}\right|$$

$$= \left|\frac{P(j\omega)\,G(j\omega)}{1 + P(j\omega)\,G(j\omega)}\,F(j\omega)\right|$$

Validation (Steps 11, 12, 13)

Once the design of the controller (and prefilter if needed) is finished, it will be convenient to analyze the performance of the complete control system under different scenarios, including: (a) frequency domain analysis of each specification for all the significant plants within the model uncertainty and (b) time domain simulations, typically using a Monte Carlo campaign for the uncertainty, first with the linear system and then with nonlinear elements (saturation, etc.).

Programs and Data

Computer-aid-design (CAD) tools have definitely facilitated the use of QFT. The MATLAB code of the interactive object-oriented QFT CAD tool developed by Garcia-Sanz et al. for ESA-ESTEC (2014) can be found at http://cesc.case.edu/OurQFTCT.htm (free download). Another popular QFT CAD tool in the 1990s, developed by Borghesani, Chait & Yaniv, can be found at http://www.terasoft.com/products/QFT/index.html.

Applications and Future Directions

- QFT has been successfully applied to a wide variety of control problems, including stable and unstable plants minimum and non-minimum phase systems, single-input single-output and multiple-input multiple-output processes, with linear and nonlinear characteristics, longtime delay, distributed parameter systems, and time-varying plants; and has been combined with feed-forward control topologies, multi-loop systems, etc. Also, QFT has been used in many real-world applications: e.g., flight control, wind energy, water treatment plants, spacecraft, power systems, mechanical systems, motion control, chemical reactors, etc. (see Garcia-Sanz and Houpis 2012; Houpis et al. 2006).
- Future research on QFT includes among others new multiple-input multiple-output techniques, nonlinear plants, distributed parameter systems, load-sharing control, etc.

Quantized Control and Data Rate Constraints

Girish N. Nair
Department of Electrical & Electronic Engineering, University of Melbourne, Melbourne, VIC, Australia

Abstract

This article briefly describes the topic of quantized control with limited data rates. The focus is on the problem of stabilizing a linear time-invariant plant over a digital channel and the associated *data rate theorems*. It is shown that the deepest results in this area require a unified treatment of its communications and control aspects.

Keywords

Control under communication constraints; Quantization; Quantized control

Introduction

One of the standard assumptions of classical control theory is that the signals sent from sensors to controllers and from controllers to actuators take continuous values with infinite precision. The advent of computer-based and digitally networked control systems challenged this assumption, since the analog plant outputs or control variables in such systems must be reduced to finite bit strings or discrete symbols for storage, manipulation, and transmission. This process of converting a continuous-valued variable into a finite-valued one is called *quantization* and entails a potentially significant loss of resolution and closed-loop performance. Quantized control is concerned with the analysis and design of control systems which feature such analog-to-digital conversions in the feedback loop.

There is a vast literature on this topic and the aim of this article is to briefly explain some of its key ideas. For reasons of space, the discussion is largely confined to the question of how to stabilize a linear time-invariant plant over a digital channel. It is shown that the deepest results here emerge from treating the communications and control aspects jointly, instead of separately. The reader is referred to the survey (Nair et al. 2007) and the references therein for a discussion of other issues such as optimality and transient performance.

Q

Quantization

Quantization has long been an object of study in communications and information theory – see Gersho and Gray (1993) and the references therein. In its simplest form, a signal $x(\cdot) : \mathbb{R} \to \mathbb{R}^n$ is first *sampled* at regular time intervals $t = 0, \tau, 2\tau, \ldots$ to yield a discrete-time signal $(x(k\tau))_{k \in \mathbb{Z}}$, with the sampling frequency $1/\tau$ chosen to be greater than the Nyquist frequency of x (i.e., twice its bandwidth). Each sample $x_k := x(k\tau)$ is then passed through a static, memoryless quantizer Q to yield a quantized discrete-time signal

$$x_k^q = Q(x_k) \in \{q^1, \ldots q^M\} \subset \mathbb{R}^n, \quad k \in \mathbb{Z}_{\geq 0}. \tag{1}$$

which can take M distinct values in $\mathbb{R}^n$. If the quantizer is known to both transmitter and receiver, each of these M values can be represented by a binary string with $\lceil \log_2 M \rceil$ bits. When the input dimension $n = 1$, the quantizer is called scalar; otherwise, it is a vector quantizer. The regions $R^i := Q^{-1}(q^i), 1 \leq i \leq M$, are called the quantizer cells and together form a partition of $\mathbb{R}^n$. Thus an M-valued quantizer is fully defined by its quantizer cells R^i and associated quantizer points $q^i, 1 \leq i \leq M$.

The quantization error or *quantizer noise* is defined as $n_k := x_k^q - x_k$. When the inputs x_k are identically distributed random variables, then a standard goal is to design Q so as to minimize the mean-square quantizer noise

$$D := \mathrm{E}[||Q(x_k) - x_k||^2], \tag{2}$$

where $\mathrm{E}[\cdot]$ is the expectation functional. This yields an optimal quantizer Q_* with cells that satisfy the nearest-neighbor property, i.e.,

$$x \in R_*^i \Rightarrow ||Q_*(x) - q_*^i|| \leq ||Q_*(x) - q_*^j||, \forall j \neq i.$$

When $|| \cdot ||$ is the Euclidean norm (possibly weighted), the quantizer cells $R_*^i, 1 \leq i \leq m$, are convex polygons and form a *Voronoi partition* of $\mathbb{R}^n$, and furthermore q_*^i is the centroid of R_*^i with respect to the stationary distribution F_X of

x_k, i.e., $q_*^i = \mathrm{E}[x_k | x_k \in R_*^i]$. As a consequence, the optimal quantizer is statistically unbiased, i.e., $\mathrm{E}[n_k] = 0$, and furthermore x_k and the quantizer noise n_k are uncorrelated at time k, i.e., $\mathrm{E}[x_k n_k^\mathrm{T}] = 0$. However, note that n_k and x_j may be correlated for $j \neq k$, and (n_k) may itself be a correlated process.

If Q is not optimal but M is large (i.e., the quantizer is *high resolution* or *fine*), then $\mathrm{E}[x_k n_k^\mathrm{T}] = \mathrm{o}(1/M)$, provided that q^i is the centroid of R^i with respect to Lebesgue measure μ and x_k has a probability density function (pdf) f_X with suitable continuity properties. The reasoning here is that each region R_i will typically be very small, so that f_X will not vary much on each R^i, yielding a conditional pdf of x_k given R_i that is approximately uniform on R_i.

When Q is a scalar uniform quantizer on an interval $[a, b]$, these considerations yield the asymptotic formula

$$D \approx (b - a)^2/(12M^2), \tag{3}$$

provided that the overload regions – i.e., the tails of $f_X(x)$ on the regions $x < a$ or $x > b$ – make negligible contributions to D. Note that this expression does not depend on the distribution of the input. For large M, it can be shown that the optimal vector quantizer has a normalized point density proportional to $f_X^{1/3}$ and yields

$$D_{\min} \approx \frac{c}{M^2} \left(\int f_X(x)^{1/3} \mathrm{d}\mu(x) \right)^3, \tag{4}$$

where the constant c depends only on n.

Quantized Control: Basic Formulation

Much of the theory of quantized control concerns finite-dimensional linear time-invariant (LTI) plants. A formulation is provided in this section to help fix ideas, for the case of a single feedback loop containing a single errorless digital channel.

Consider the discrete-time plant

$$x_{k+1} = Ax_k + Bu_k + v_k, \quad y_k = Fx_k + w_k, \tag{5}$$

where at every time $k \in \mathbb{Z}_{\geq 0}$, $x_k \in \mathbb{R}^n$ is the state with x_0 unknown, $u_k \in \mathbb{R}^m$ is the control input, $y_k \in \mathbb{R}^p$ is the measured output, $v_k \in \mathbb{R}^n$ is unknown process noise, $w_k \in \mathbb{R}^p$ is unknown measurement noise, and A, B, and F are constant known matrices of appropriate dimensions. For the problem to be well posed, assume that the matrix pairs (A, B) and (F, A) are, respectively, reachable and observable. Suppose that the output sensors communicate with the controller over a digital channel that can carry one symbol s_k from a finite, possibly time-varying alphabet $\mathbb{S}_k$ of cardinality $M_k \geq 1$ during the $(k + 1)$-th sampling interval. Assume for simplicity that the channel is errorless, with negligible propagation delay. The asymptotic average rate at which the channel transports data may then be defined as

$$R := \varliminf_{k \to \infty} \frac{1}{k} \sum_{j=0}^{k-1} \log_2 M_j \quad \text{(bits/sample)}. \quad (6)$$

Note that if the channel alphabet $\mathcal{S}_k$ is constant or varies periodically with k, the inferior limit reduces to a straight limit.

In full generality, each transmitted symbol may depend on all past and present measurements and past symbols,

$$s_k = \gamma_k(y_0^k, s_0^{k-1}) \in \mathcal{S}_k, \quad \forall k \in \mathbb{Z}_{\geq 0}, \quad (7)$$

where γ_k is the coder mapping at time k. At time k the controller has $s_0, \ldots, s_k$ available and then applies a control law of the general form

$$u_k = \delta_k(s_0^k) \in \mathbb{R}^m, \quad \forall k \in \mathbb{Z}_{\geq 0}, \quad (8)$$

where δ_k is the controller mapping at time k.

In practice, additional memory or structural constraints are usually placed on the general coding and control rules (7) and (8). For instance, if a static quantizer of the form (1) is used, then the coding alphabet $\mathcal{S}_k \equiv \mathcal{S}$ will be constant and $s_k \equiv \gamma(y_k)$ will represent the index of the quantizer cell that contains y_k. Similarly, a static, memoryless controller is captured by setting $u_k = \delta(s_k)$ in (8).

Finite-dimensional coding and control laws may be formulated by defining internal coder and controller states ψ_k^γ and ψ_k^δ with local updates of the form

$$s_k = \gamma\left(y_k, \psi_{k-1}^\gamma\right), \quad \psi_k^\gamma = \phi\left(s_k, \psi_{k-1}^\gamma\right), \quad (9)$$

$$\psi_k^\delta = \eta\left(s_k, \psi_{k-1}^\delta\right), \quad u_k = \delta\left(\psi_k^\delta\right). \quad (10)$$

If the states ψ_k^γ and ψ_k^δ are finite valued, then the coding and control laws are called *finite-state*.

Additive Noise Model

Early approaches to quantized control modeled quantization errors as additive noise, in order to allow the use of well-developed tools from linear stochastic control (Curry 1970). While this was reasonable at high quantizer resolution, it failed to capture two key properties.

A simple example illustrates this. Consider a scalar, noiseless, fully observed, unstable LTI plant – i.e., (5) with $n = 1$, $A = a$ with $|a| > 1$, B, $C = 1$, and w_k, $v_k = 0$ – where x_0 is a random variable. Under static, high-resolution uniform quantization, the data available to the controller is expressed as a noisy linear measurement

$$y_k' := Q(x_k) = x_k + n_k, \quad k \in \mathbb{Z}_{\geq 0},$$

where the quantizer error process (n_k) is treated as zero mean white noise uncorrelated with (x_k) and having constant variance given by (3).

The first shortcoming of this approach is that it precludes the possibility of asymptotic mean-square stability, which would effectively require the controller to estimate the initial state x_0 with a mean-square error diminishing strictly faster than a^{-2k}. This turns out to be impossible under the uncorrelatedness assumption and the constraint $|a| > 1$.

However, in the seminal paper (Delchamps 1990), it was shown that asymptotic stability could in fact be achieved, by using a nonlinear controller that exploited the correlation between successive quantizer errors. To see this, suppose

that the unknown initial state x_0 is confined to a known interval $[-l_0, l_0]$. At time $k \geq 0$, suppose that $l_k \geq 0$, $k = 1, 2, \ldots$ represent bounds to be determined on the future states x_k. Let Q be a static one-bit quantizer – i.e., with $M = 2$ – such that $Q(x) = 1$ if $x \geq 0$ and $Q(x) = -1$ if $x < 0$. At time k let $u_k = -0.5al_k Q(x)$ so that

$$x_{k+1} = \begin{cases} a(x_k - 0.5l_k) & \text{if } 0 \leq x_k \leq x_k \\ a(x_k + 0.5l_k) & \text{if } -l_k \leq x_k < 0 \end{cases}.$$

$$\Rightarrow |x_{k+1}| \leq 0.5|a|l_k =: l_{k+1}.$$

If $|a| < 2$ then $l_k \to 0$, and asymptotic stability is achieved uniformly and with exponential convergence.

However, the main drawback of the additive white noise model is that it does not predict the loss of closed-loop stability that can result when the quantizer resolution is too coarse. This is because the number M of quantizer points only serves to determine the variance of the additive noise n_k: reducing M increases the variance of n_k and the mean-square states, but they remain bounded over time. In contrast, a rigorous analysis reveals that stability is impossible by any means, linear or nonlinear, when M drops below a certain threshold.

Numerous proofs of this loss of stability exist. In a stochastic setting, the argument is based on fixing the coder and controller and expanding out the closed-loop dynamics of the scalar LTI plant to write

$$x_k = a^k x_0 - a^k z_k \qquad (11)$$

where $z_k := -a^{-k} \sum_{j=0}^{k-1} a^{k-j-1} u_j$. As z_k is a function of $s_0^{k-1} \in \mathcal{S}^k$, it can take at most M^k values. Furthermore, in the absence of noise, it is fully determined by x_0, for a given coding and control policy (7) and (8). Thus z_k can be regarded as the output $Q'_k(x_0)$ of an M^k-valued quantizer. Substituting this into (11) yields

$$x_k = a^k(x_0 - Q'_k(x_0)).$$

From the asymptotic quantizer result (4), it then follows that for large k,

$$\mathrm{E}[x_k^2] \geq c \frac{a^{2k}}{M^{2k}} \left(\int f_{X_0}(x)^{1/3} \mathrm{d}\mu(x) \right)^3.$$

Thus a necessary condition for asymptotic mean-square stabilizability is that $M > |a|$ – see Nair and Evans (2000) for details.

The Data Rate Theorem

The discussions above emphasized the need for a more rigorous approach to quantized control. In the literature, the necessary condition $M > |a|$ was first derived in a nonrandom setting, where it was shown to be both sufficient and necessary to be able to ensure uniform stability (Baillieul 1999; Wong and Brockett 1999).

The sufficiency argument is constructive. Let Q be an M-level uniform quantizer on $[-1, 1]$, with cells formed by partitioning $[-1, 1]$ into M subintervals $R^1, \ldots, R^M$ of equal length and setting $Q(z)$ to be the midpoint of R^i when $z \in R^i$. Suppose that at time k the unknown state x_k lies in a known interval $[-l, l]$, and set $u_k = -alQ(x_k/l)$. Thus

$$|x_{k+1}| = |a||x_k - lQ(x_k/l)|$$
$$= |a|l \left| \frac{x}{l} - Q\left(\frac{x}{l}\right) \right| \leq |a|\frac{l}{M}.$$

When $M > |a|$, the right-hand side $< l$. Thus $x_{k+1} \in [-l, l]$ as well, and boundedness is achieved. Uniform asymptotic stability can be achieved by replacing the constant parameter l in the argument above with a time-varying bound l_k, updated as $l_{k+1} = |a|l_k/M \to 0$.

The necessity argument is based on volume partitioning. The basic idea is to fix an arbitrary coding and control policy and let m_k be the Lebesgue measure of the set of values that x_k can take at time $k \in \mathbb{Z}_{\geq 0}$. After k time steps, the plant dynamics expand this uncertainty volume m_0 by a factor $|a|^k$. However, the coder effectively divides this region into M^k disjoint, exhaustive pieces, each of which is shifted by the controller. As Lebesgue measure is translation invariant, it then

follows that $m_k \geq |a|^k m_0 / M^k$. Consequently M must exceed $|a|$ if the closed loop is uniformly asymptotically stable.

The tight criterion $M > |a|$, or equivalently $R > \log_2 |a|$, was the first instance of the *data rate theorem*. Volume-partitioning arguments and Jordan canonical forms can be used to generalize it to LTI plants with vector-valued states, yielding the necessary and sufficient condition

$$R > \sum_{i:|\lambda_i| \geq 1} \log_2 |\lambda_i| =: H, \qquad (12)$$

where $\lambda_1, \ldots, \lambda_n$ are the eigenvalues of A. This criterion is remarkably universal, having been shown to be tight for a variety of settings and objectives: e.g., for asymptotic r-th moment stabilizability with random, unbounded x_0 and no process or measurement noise (Nair and Evans 2003); uniform stabilizability with bounded x_0 and no process or measurement noise (Baillieul 2002); uniform stabilizability with bounded initial state, process, and measurement noise (Hespanha et al. 2002; Tatikonda and Mitter 2004); and mean-square stabilizability with random, unbounded initial state, process, and measurement noise (Nair and Evans 2004).

The deep nature of (12) becomes even clearer when it is noted that the right-hand side of (12) coincides with the intrinsic entropy generation rate H of the (open-loop) plant, in both the Kolmogorov-Sinai and topological senses; that is, it describes the growth rate of the number of distinguishable state trajectories. Thus the data rate theorem states that stability is possible iff the communication rate in the feedback loop exceeds the rate at which the plant generates uncertainty. This interpretation leads to the notion of *feedback entropy* (see cross-reference to article by C. Kawan).

Zooming Quantized Control

When the plant noise and initial state of the plant (5) are bounded, stability (in a uniform sense) can be guaranteed by applying a linear observer to track the plant states with bounded error and then applying a suitable static, memoryless coding and control policy on the observer states x_k^o.

However, if the noise or initial state has unbounded support – e.g., when they are Gaussian or when prior bounds on them are not known – then stability cannot be achieved by any such static memoryless scheme or indeed by any scheme where the control inputs (8) are bounded (Nair and Evans 2004). The explanation is simple: due to the infinite support, there is a nonzero probability that the propagated state Ax_t will be beyond reach of the control input at some time t. The unstable plant dynamics then amplify this shortfall, causing the same phenomenon to occur with increasing probability at subsequent times and inevitably leading to instability.

One solution is to use a *zooming quantizer*, i.e., having a dynamic range $l_k > 0$ that is not bounded a priori but expands or contracts according to the most recent symbol (Brockett and Liberzon 2000). In the noiseless case, if this symbol corresponds to the "overload region" of the quantizer (as indicated by a special symbol), then the range is updated as $l_{k+1} := \phi_{out} l_k$, where $\phi_{out} > 1$ is the "zoom-out" factor. Otherwise $l_{k+1} := \phi_{in} l_k$, where $\phi_{in} < 1$ is the "zoom-in" coefficient.

In the communications literature such schemes are called *adaptive quantizers* (Goodman and Gersho 1974). If ϕ_{out} is sufficiently large compared to the unstable open-loop eigenvalues, and if ϕ_{in} is not too small, then global asymptotic stability ensues. With unbounded noise in the plant, variants of this scheme guarantee mean-square stability at any data rate satisfying (12) (Nair and Evans 2004) or *input-to-state stability* (Liberzon and Nesic 2007).

Zooming quantization is an important example of a finite-dimensional coder-controller (9) and (10), with l_k playing the role of an internal state variable. As the range update is driven by the symbols, both coder and controller can each generate identical copies of l_k, provided that there are no errors in the channel and they both start from the same initial range l_0. The important issue of how to design a scheme that can cope with mismatched initial internal states or a small level of channel errors is as yet largely unexplored.

Erroneous Digital Channels

The information-theoretic aspects of quantized control become especially pronounced when the channel is not error-free. In this case, the data rate theorem (12) can be extended, but in ways that are highly dependent on the precise setting and stability objective.

A common figure of merit for a stochastic discrete memoryless channel (DMC) is its *ordinary capacity C*. This is defined operationally as the largest block-code bit rate that can be transmitted across the channel with negligible probability of decoding error, and also coincides with the largest rate of Shannon information across the channel (Shannon 1948). For a noiseless LTI plant with random initial state controlled over a DMC, the condition $C > H$ is a tight criterion for almost sure (a.s.) asymptotic stabilizability (Matveev and Savkin 2007a). This is a natural generalization of (12).

On the other hand, if the objective is to bound the state moments of a scalar LTI plant subject to bounded process noise, then the achievability of this goal is determined by the *anytime capacity C_{any}* (Sahai and Mitter 2006): this is essentially given by the fastest decay rate of the decoding error probability.

However, if the aim is a.s. boundedness of an LTI plant with random initial state and bounded, nonstochastic process noise, then the stabilizability criterion changes again to $C_{0f} > H$ (Matveev and Savkin 2007b). Here C_{0f} is the *zero-error feedback capacity* of the channel, defined as the largest block-code bit rate that can be transmitted across the channel with *exactly zero* probability of decoding error and with perfect channel feedback (Shannon 1956).

As $C_{0f} < C_{any} < C$ for most channels, these conditions do not coincide. This suggests that there is no universal, operationally relevant information theory for feedback control over error-prone channels: such a theory must instead be tailored to match the underlying objectives and assumptions. For systems with nonstochastic disturbances, preliminary steps in this direction have been taken in Nair (2012, 2013). The reader is also referred to You and Xie (2011) and Minero et al. (2013) for information-theoretic analyses of stochastic linear systems controlled via Markov channels.

Summary and Future Directions

This article described the key elements of quantized control with finite data rates, emphasizing the interplay between coding and control. A great deal is now known about the fundamental limitations on stability in quantized control systems consisting a single feedback loop. Two major directions for future research suggest themselves:

– Little work has been done on designing optimal coding and control schemes or determining optimal costs at a given rate, apart from one or two special cases and structural results – see Nair et al. (2007) and the references therein. It is very unlikely that explicit, closed-form solutions will be possible. However, numerical approaches based on the Lloyd-Max algorithm, particle filtering, and model-predictive control may prove fruitful.

– Networked control systems usually consist of a number of subsystems interconnected over a network. Furthermore, in multi-agent systems the main objective may not be stability, but rather coordination or consensus to a common state. Comparatively little is known about the data rate requirements and information-theoretic aspects of these problems.

Randomized Methods for Control of Uncertain Systems

Fabrizio Dabbene and Roberto Tempo
CNR-IEIIT, Politecnico di Torino, Torino, Italy

Abstract

In this article, we study the tools and methodologies for the analysis and design of control systems in the presence of random uncertainty. For analysis, the methods are largely based on the Monte Carlo simulation approach, while for design new randomized algorithms have been developed. These methods have been successfully employed in various application areas, which include systems biology; aerospace control; control of hard disk drives; high-speed networks; quantized, embedded, and electric circuits; structural design; and automotive and driver assistance.

Keywords

Chernoff bound; Hoeffding inequality; Monte Carlo simulation; Randomization algorithms

Preliminaries

Randomized methods for control deal with the design of uncertain and complex systems. They have been originally developed for linear systems affected by structured uncertainty, usually expressed in the so-called $M - \Delta$ configuration. A similar approach may be followed when dealing with uncertainty in other contexts, such as uncertainty in the environment (random disturbances) or even when there is no uncertainty in the problem formulation, but the complexity of the problem is such that randomized methods may be the best approach, since these methods are known to break the curse of dimensionality, see Tempo et al. (2013) for details.

For the sake of simplicity, we consider here an uncertain plant transfer function $P(s, q)$ affected by parametric uncertainty

$$q = [q_1 \ldots q_\ell]^T$$

bounded in a set $\mathbb{Q} \subset \mathbb{R}^\ell$. The objective is to design the parameters $\theta \in \mathbb{R}^n$ of a controller transfer function $C(s, \theta)$ so to guarantee robustly some desired performance. This is reformulated as the problem of finding a design satisfying some *uncertain constraints* of the form

$$f(\theta, q) \leq \text{ for all } q \in \mathbb{Q}.$$

In other words, the goal is to design a robust controller which satisfies the uncertain constraints. Specific examples of these constraints include an $\mathcal{H}_\infty$ or $\mathcal{H}_2$ norm bound on the closed-loop sensitivity function or time-domain specifications.

Since this objective may be too hard to achieve in many situations, we are relaxing it as follows:

we would like to design controller parameters $\theta \in \mathbb{R}^n$ such that a certain *violation* is allowed, i.e.,

$$\begin{cases} f(\theta, q) \leq 0 \text{ for all } q \in \mathbb{Q}_{\text{good}}; \\ f(\theta, q) > 0 \text{ for all } q \in \mathbb{Q}_{\text{bad}} \end{cases}$$

where the good and bad sets satisfy the equations

$$\begin{cases} \mathbb{Q}_{\text{good}} \cup \mathbb{Q}_{\text{bad}} = \mathbb{Q}; \\ \mathbb{Q}_{\text{good}} \cap \mathbb{Q}_{\text{bad}} = \varnothing, \end{cases}$$

and the goal is to guarantee that the bad set $\mathbb{Q}_{\text{bad}}$ is "small" enough. To state this concept more precisely, we assume that $q \in \mathbb{Q}$ is a random vector with given probability density function (pdf), and we introduce the probability of violation and the controller reliability.

Definition 1 (Probability of Violation and Reliability) The probability of violation for the controller parameters $\theta \in \mathbb{R}^n$ is defined as

$$V(\theta) \doteq \text{Prob}\{q \in \mathbb{Q} : f(\theta, q) > 0\}.$$

The reliability of the design $\theta \in \mathbb{R}^n$ is given by

$$R(\theta) = 1 - V(\theta).$$

In this context, we are satisfied if, given a violation level $\propto \in (0, 1)$, the probability of violation is sufficiently small, i.e., $V(\theta) \leq \propto$. We remark that relaxing the requirement of robust satisfaction of the uncertain constraints $f(\theta, q) \leq 0$ to a probabilistic one (by means of the probability of violation) is not helpful computationally because computing *exactly* the probability $V(\theta)$ is very hard in general because it requires to solve a multidimensional integral over the nonconvex domain defined by $f(\theta, q) > 0$, with $q \in \mathbb{Q} \subset \mathbb{R}^\ell$. The problem is then resolved introducing Monte Carlo randomized algorithms (formally defined in the next section). This is a computational approach which leads to solutions which are often denoted as PAC (probably approximately correct) (Vidyasagar 2002).

More precisely, for fixed design $\theta \in \mathbb{R}^n$, to compute a Monte Carlo approximation based on N random simulations, we generate N independent identically distributed (iid) random

samples of $q \in \mathbb{Q}$, called the *multisample*, of the uncertainty q according to the given probability density function

$$q^{(1...N)} = \left\{ q^{(1)}, \ldots, q^{(N)} \right\} \in \mathbb{Q}^N.$$

The cardinality N of the multisample $q^{(1...N)}$ is often referred to as the *sample complexity* (Vidyasagar 2001). The empirical violation of the design θ is then defined.

Definition 2 (Empirical Violation) *For given* $\theta \in \mathbb{R}^n$, *the empirical violation of* $V(\theta, q)$ *with respect to the multisample* $q^{(1...N)} = \left\{ q^{(1)}, \ldots, q^{(N)} \right\} \in \mathbb{Q}^N$ *is given by*

$$\hat{V}_N\left(\theta, q^{(1...N)}\right) \doteq \frac{1}{N} \sum_{i=1}^N \mathbb{I}_f\left(\theta, q^{(i)}\right)$$

where $\mathbb{I}_f\left(\theta, q^{(i)}\right)$ is the indicator function

$$\mathbb{I}_f\left(\theta, q^{(i)}\right) \doteq \begin{cases} 0 \text{ if } f\left(\theta, q^{(i)}\right) \leq 0 \\ 1 \qquad \text{otherwise.} \end{cases}$$

Monte Carlo Randomized Algorithms for Analysis

In this section, we study Monte Carlo randomized algorithms for analysis, i.e., when the controller parameters are fixed, and in particular we concentrate on a PAC computation of the probability of violation. In agreement with classical notions in computer science (Mitzenmacher and Upfal 2005; Motwani and Raghavan 1995), a randomized algorithm (RA) is formally defined as an algorithm that *makes random choices* during its execution to produce a result. This implies that, even for the same input data, the algorithm might produce different results at different runs, and, moreover, the results may be incorrect. Therefore, statements regarding properties of these algorithms are necessarily of probabilistic nature.

Formally, the probabilistic parameters ε, $\delta \in (0, 1)$ called *accuracy* and *confidence,* respectively, are introduced. For any θ, the PAC approach provides an empirical violation which is

an approximation $\hat{V}_N\left(\theta, q^{(1...N)}\right)$ to $V(\theta)$ within accuracy ε, and this event holds with confidence $1 - \delta$.

Monte Carlo Randomized Algorithm

Given a design $\theta \in \mathbb{R}^n$, a Monte Carlo randomized algorithm (MCRA) is a randomized algorithm that provides an approximation $\hat{V}_N\left(\theta, q^{(1...N)}\right)$ to $V(\theta)$ based on the multisample $q^{(1...N)}$. Given accuracy ε and confidence δ, the approximation may be incorrect, i.e.,

$$\left| V(\theta) - \hat{V}\left(\theta, q^{(1...N)}\right) \right| > \epsilon$$

but the probability of such an event is bounded, and it is smaller than δ.

In general, the results obtained by an MCRA as well as its running time would be different from one run to another since the algorithm is based on random sampling. As a consequence, the computational complexity of such an algorithm is usually measured in terms of its expected running times. MCRA are efficient because the expected running time is of polynomial order in the problem size (Tempo et al. 2013). One-sided and two-sided Monte Carlo randomized algorithms may be also defined (Tempo and Ishii 2007).

To derive the probabilistic properties of MCRA, we need to state the so-called Hoeffding inequality, which provides a bound on the error between the probability of violation and the empirical violation (Vidyasagar 2002).

Two-Sided Hoeffding Inequality

For fixed $\theta \in \mathbb{R}^n$ and $\varepsilon \in (0, 1)$, we have

$$\text{Prob}\left\{ q^{(1...N)} \in \mathbb{Q}^N : \left| V(\theta) - \hat{V}\left(\theta, q^{(1...N)}\right) \right| \right.$$
$$\left. > \epsilon \right\} \leq 2e^{-2N\epsilon^2}.$$

For fixed accuracy ε, we observe that the right-hand side of this equation approaches zero exponentially. Furthermore, if we bound the right-hand side of this equation with confidence δ, we immediately obtain the classical (additive)

Chernoff bound (Chernoff 1952) which is stated next.

Chernoff Bound

For any $\varepsilon \in (0, 1)$ and $\delta \in (0, 1)$, if

$$N \geq \frac{1}{2\epsilon^2} \log \frac{2}{\delta}$$

then, with probability greater than $1 - \delta$, we have

$$\left| V(\theta) - \hat{V}\left(\theta, q^{(1...N)}\right) \right| \leq \epsilon.$$

The Chernoff bound provides an indication of the required sample size, i.e., it provides the so-called sample complexity. More precisely, the sample complexity of a randomized algorithm is defined as the minimum cardinality of the multisample $q^{(1...N)}$ that needs to be drawn in order to achieve the desired accuracy ε and confidence δ. Notice that the confidence enters the Chernoff bound in a logarithmic fashion, while accuracy enters quadratically, and therefore, it is much more expensive computationally. Other large deviation inequalities and sample complexity bounds are discussed in the literature, including in particular the (multiplicative) Chernoff bound and the log-over-log bound for computing the so-called empirical maximum (Tempo et al. 1997). We refer to Vidyasagar (2002) for additional details.

Remark 1 (Las Vegas Randomized Algorithms) Las Vegas randomized algorithms (LVRA) are based on random samples generated according to a *discrete* probability density function, instead of a continuous pdf as in the case of Monte Carlo. Therefore, contrary to MCRA, LVRA provide the "correct answer" with probability one because the entire search space can be fully explored. However, because of randomization, the running time of an LVRA is random (similarly to MCRA) and may be different in each execution. Hence, it is of interest to study the expected running time of the algorithm. It is noted that the expectation is with respect to the random samples generated during the execution of the algorithm and not to the problem data. Classical examples of LVRA are within computer science

and include the well-known randomized quick-sort (RQS) algorithm for ranking numbers, which is implemented in a C library of the UNIX operating system (Knuth 1998). Other more recent developments in systems and control regarding these algorithms are for the PageRank computation in the Google search engine (Ishii and Tempo 2010), consensus over large-scale networks (Fagnani and Zampieri 2008), localization and coverage control of robotic networks (Bullo et al. 2012), and opinion dynamics (Frasca et al. 2013). These problems are generally formulated in a graph theoretic setting consisting of nodes and links, and either the nodes or the links are randomly selected according to a given "local" protocol (often called gossip) based on a given discrete pdf.

Randomized Algorithms for Control Design

This section deals with control problems which require computing a design $\theta \in \mathbb{R}^n$ satisfying some probabilistic properties on the uncertain constraints $f(\theta, q)$. Two classes of problems, feasibility and optimization, are considered.

Feasibility Problem

Given uncertain constraints $f(\theta, q)$ and level $\propto \in (0, 1)$, compute $\theta \in \mathbb{R}^n$ such that

$$V(\theta) = \text{Prob}\{q \in \mathbb{Q} : f(\theta, q) > 0\} \leq \propto . \quad (1)$$

The second problem relates to the optimization of a linear function of the design parameters under probability constraints.

Optimization Problem

Given uncertain constraints $f(\theta, q)$, a linear objective function $c^T \theta$ and level $p \in (0, 1)$, solve the constrained optimization problem

$$\min_\theta \quad c^T \theta$$

$$\text{subject to } V(\theta) = \text{Prob}\{q \in \mathbb{Q} : f(\theta, q) > 0\}$$

$$\leq p. \quad (2)$$

Optimization problems subject to constraints of the form $V(\theta) = \text{Prob}\{q \in \mathbb{Q} : f(\theta, q) > 0\} \leq \propto$ are often called chance constraint optimization (Uryasev 2000).

Most of the algorithms that have been studied in the literature follow two main paradigms and are often based on the following convexity assumption.

Convexity Assumption

The uncertain constraint $f(\theta, q)$ is convex in θ for any fixed value of $q \in \mathbb{Q}$.

The two solution paradigms that have been proposed are now summarized. The algorithms have been implemented in the Toolbox RACT (Randomized Algorithms Control Toolbox) for probabilistic analysis and control design in the presence of uncertainty (Tremba et al. 2008).

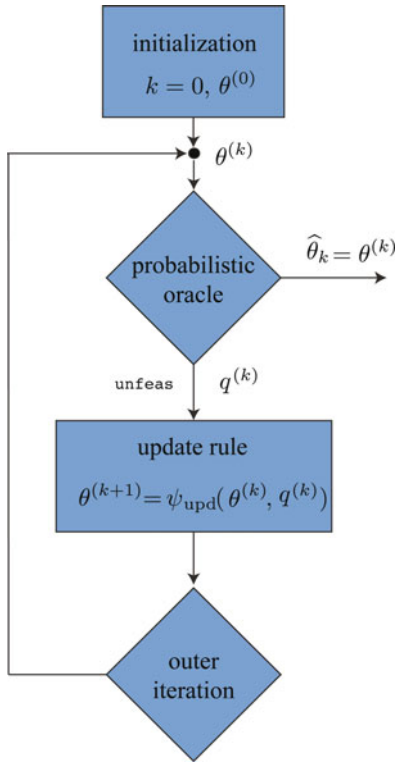
Paradigm 1 (Sequential Approach)

Under the convexity assumption, we study the Feasibility Problem (1). The algorithms presented in the literature (see, e.g., (Calafiore et al. 2011) for finding a probabilistic feasible design) follow a general iterative scheme (Fig. 1), which consists of successive randomization steps to handle uncertainty and optimization steps to update the design parameters. In particular, these algorithms share two fundamental ingredients:

1. A *probabilistic oracle* which performs a random check, with the objective to assess whether the probability of violation $V(\theta^{(k)})$ of the current candidate solution $\hat{\theta}^{(k)}$ is smaller than a given level p and returns a *certificate* of unfeasibility, that is, a value $q^{(k)}$ such that $f(\hat{\theta}^{(k)}, q^{(k)}) > 0$, when the candidate solution is found unfeasible

2. An *update rule* ψ_{upd} which exploits the convexity of the problem for constructing a new candidate solution $\hat{\theta}^{(k+1)}$ based on the probabilistic oracle outcome

In this paradigm, the algorithm returns a design $\hat{\theta}_k$ such that

$$V\left(\hat{\theta}_k\right) = \text{Prob}\left\{q \in \mathbb{Q} : f\left(\hat{\theta}_k, q\right) > 0\right\} \leq \rho$$


Randomized Methods for Control of Uncertain Systems, Fig. 1 Paradigm for sequential design consisting of probabilistic oracle and update rule

In this paradigm, the algorithm returns in one-shot a design $\hat{\theta}_N$ and the sample complexity N such that

$$V\left(\hat{\theta}_N\right) = \mathrm{Prob}\left\{q \in \mathbb{Q} : f\left(\hat{\theta}_N, q\right) > 0\right\} \leq \rho$$

is larger than $1-\delta$. That is, the violation probability associated to the design $\hat{\theta}_N$ is smaller than the level p, and this event holds with large confidence $1 - \delta$.

Concluding Remarks

Other probabilistic approaches have been proposed in the literature for control design, which are not based on the convexity assumption. A noticeable example is the strategy based on statistical learning theory (Valiant 1984; Vapnik 1998) which has the objective to design a controller without any convexity assumptions (Alamo et al. 2009). In particular, in Alamo et al. (2013), the general class of sequential probabilistic validation (SPV) algorithms has been introduced. A specific SPV algorithm tailored to scenario problems, providing a sequential scheme for dealing with the optimization problem, has been recently studied in Chamanbaz et al. (2013).

Cross-References

is larger than $1-\delta$. That is, the violation probability associated to the design $\hat{\theta}_k$ is smaller than the level ρ, and this event holds with large confidence $1 - \delta$.

Paradigm 2 (Scenario Approach)
Under the convexity assumption, we study the optimization problem (2). We remark that, even under these assumptions, solving this problem is very hard computationally because the probabilistic constraint is nonconvex. To alleviate this difficulty, we reformulate problem (2) as a so-called scenario problem introduced in Calafiore and Campi (2006), which is now described.

For randomly extracted scenarios $q^{(1\ldots N)}$, this approach requires to compute $\theta \in \mathbb{R}^n$ that solves the convex optimization problem subject to a finite number of sampled constraints

$$\hat{\theta}_N = \begin{array}{ll} \min_\theta & c^T \theta \\ \text{subject to} & f\left(\theta, q^i\right) \leq 0, \ i = 1, \ldots, N \end{array} \tag{3}$$

Abstract

When a state variable description of a linear system is known, then its input–output behavior can be easily realized by interconnecting simpler components. The problem of realization refers to the following: given an input–output description such as the impulse response, or the transfer function in the case of time-invariant systems, find a state variable description, the impulse response of which is the given one. Existence and minimality conditions are discussed. We are interested in realizations of minimum order which is the case when the realization is both controllable and observable. Realizations in both the continuous-time and discrete-time systems are discussed.

Keywords

Controllability; Irreducible; Minimal order; Observability; Realizations

Introduction

The problem of system realization is as follows: given an external description of a linear system, specifically its impulse response (or its transfer function in the case of a time-invariant system), determine an internal state variable description that generates the given impulse response (or the

transfer function). The name reflects the fact that if a (continuous-time) state variable description is known, an operational amplifier circuit can be easily built to realize (actually simulate) the system response.

Before we discuss realizations, we review the key relations between internal state variable and external impulse response or transfer function descriptions.

Consider a system described by

$$\dot{x} = A(t)x + B(t)u, \quad y = C(t)x + D(t)u, \tag{1}$$

where $x(t)$, the state vector, is a column vector of dimension n $(x(t) \in \mathbb{R}^n)$ and $u(t) \in \mathbb{R}^m$, $y(t) \in \mathbb{R}^p$ are the inputs and outputs of the system. $A(t) \in \mathbb{R}^{n \times n}$, $B(t) \in \mathbb{R}^{n \times m}$, $C(t) \in \mathbb{R}^{p \times n}$, $D(t) \in \mathbb{R}^{p \times m}$ with entries continuous functions. The output response is given by

$$y(t) = C(t)\Phi(t, t_0)x_0 + \int_0^t H(t, \tau)u(\tau)d\tau, \tag{2}$$

where $\Phi(t, t_0)$ is the $n \times n$ transition matrix of $\dot{x} = A(t)x$, $x(t_0) = x_0$ is the initial condition, and $H(t, \tau)$ is the $p \times m$ impulse response matrix given by

$$H(t, \tau) = \begin{cases} C(t)\Phi(t, \tau)B(t) \\ \quad + D(t)\delta(t - \tau) & t \geq \tau, \\ 0 & t < \tau, \end{cases} \tag{3}$$

where $\delta(t - \tau)$ is the impulse (delta or Dirac) function applied at time $t = \tau$. Recall that $H(t, \tau)$ denotes the response at time t when an impulse input is applied at time τ assuming zero initial conditions.

In the time-invariant system, (1) becomes

$$\dot{x} = Ax + Bu, \quad y = Cx + Du, \tag{4}$$

and the output response in this case is

$$y(t) = Ce^{At}x_0 + \int_0^t H(t, \tau)u(\tau)d\tau, \tag{5}$$

where, without loss of generality, the initial time t_0 was taken to be zero. In this case, the impulse response is

$$H(t, \tau) = \begin{cases} Ce^{A(t-\tau)}B + D\delta(t - \tau) & t \geq \tau, \\ 0 & t < \tau. \end{cases} \tag{6}$$

Recall that time invariance implies that $H(t, \tau) = H(t - \tau, 0)$, and so τ, which is the time an impulse input is applied to the system, can be taken to be zero $(\tau = 0)$, without loss of generality, to give $H(t, 0)$. The transfer function of the system is the (one-sided or unilateral) Laplace transform of $H(t, 0)$, namely,

$$H(s) = \mathcal{L}[H(t, 0)] = C(sI - A)^{-1}B + D. \tag{7}$$

A realization of $H(t, \tau)$ is any state variable description (1), $\{A(t), B(t), C(t), D(t)\}$, the impulse response of which is $H(t, \tau)$, that is, (3) is satisfied, similarly for the time-invariant case when (6) is satisfied.

In the time-invariant case, a realization is commonly defined in terms of the transfer function matrix $H(s)$. Then a realization of $H(s)$ is any state variable description (4), $\{A, B, C, D\}$, the transfer function of which is $H(s)$, that is, (7) is satisfied.

There are alternative conditions under which a set of $\{A, B, C, D\}$ is a realization of some $H(s)$. To this end, expand $H(s)$ in a Laurent series to obtain

$$H(s) = H_0 + H_1 s^{-1} + H_2 s^{-2} + \cdots. \tag{8}$$

The matrices H_i, $i = 0, 1, 2, \ldots$ are called *Markov parameters* of the system and can be determined as follows:

$$H_0 = \lim_{s \to \infty} H(s), \quad H_1 = \lim_{s \to \infty} s(H(s) - H_0),$$

$$H_k = \lim_{s \to \infty} s^k (H(s) - \Sigma_{i=0}^{k-1}H_i s^{-i}), \quad k \geq 1.$$

It can be shown that a set $\{A, B, C, D\}$ is a realization of $H(s)$ if and only if

$$H_0 = D \text{ and } H_i = CA^{i-1}B, \quad i = 1, 2, \ldots. \tag{9}$$

Below we introduce conditions for the existence of a realization given $H(t, \tau)$ or $H(s)$.

Note that if a realization does exist, then there is an infinite number of realizations. One could see this, for example, by considering equivalent descriptions of a realization – all have the same impulse response or transfer function.

Existence and Minimality

It can be shown that $H(t, \tau)$ is realizable as the impulse response of a system described by (1) if and only if $H(t, \tau)$ can be decomposed into

$$H(t, \tau) = M(t)N(\tau) + D(t)\delta(t - \tau), \quad (10)$$

for $t \geq \tau$, where M, N, and D are $p \times n$, $n \times m$, and $p \times m$ matrices, respectively, with continuous real-valued entries and with n finite. If in addition to (10), $M(t)$ and $N(t)$ are differentiable and

$$H(t, \tau) = H(t - \tau, 0), \quad (11)$$

then $H(t, \tau)$ is realizable as the impulse response of a system described by a time-invariant system (4).

In the time-invariant case, it is more common to work with a given transfer function $H(s)$. Then $H(s)$ is realizable, as the transfer function matrix of a time-invariant system described by (4), if and only if $H(s)$ is a matrix of rational functions and satisfies

$$\lim_{s \to \infty} H(s) < \infty, \quad (12)$$

that is, if and only if $H(s)$ is a proper rational matrix or equivalently if and only if

$$\lim_{s \to \infty} H(s) = D \quad (13)$$

is a constant.

We are interested in realizations (4) of a given transfer function matrix $H(s)$ of least order n ($A \in \mathbb{R}^{n \times n}$), called minimal or irreducible realizations of $H(s)$.

The following two results completely solve the minimal realization problem.

Theorem 1 *An n-dimensional realization $\{A, B, C, D\}$ of $H(s)$ is minimal (irreducible, of least order) if and only if it is both reachable (or controllable) and observable.*

Note that if (A, B) is not controllable, then by separating the controllable and uncontrollable parts of the system by an equivalence transformation and taking only the controllable part, one can still obtain $H(s)$ because the uncontrollable part of the system cancels out in $H(s)$. Similarly for observability. So controllability and observability are necessary conditions for minimality. It can be shown that they are also sufficient.

Theorem 2 *If a minimal realization of order n is found, then any other minimal realization may be obtained via equivalence transformation.*

Specifically, if $\{A, B, C, D\}$ and $\{\bar{A}, \bar{B}, \bar{C}, \bar{D}\}$ are realizations of $H(s)$ and $\{A, B, C, D\}$ is minimal, then $\{\bar{A}, \bar{B}, \bar{C}, \bar{D}\}$ is also minimal if and only if there exists a nonsingular matrix P such that

$$\bar{A} = PAP^{-1}, \ \bar{B} = PB, \ \bar{C} = CP^{-1}, \ \bar{D} = D. \quad (14)$$

Discrete-Time Linear Systems

The definitions and results for the discrete-time case are completely analogous to the ones in the continuous-time case. They are summarized below for completeness.

Consider systems described by

$$\begin{aligned} x(k + 1) &= A(k)x(k) + B(k)u(k), \\ y(k) &= C(k)x(k) + D(k)u(k). \end{aligned} \quad (15)$$

The output response is

$$y(k) = C(k)\Phi(k, k_0)x_0 + \sum_{i=k_0}^{k-1} H(k, i)u(i), \ k > k_0, \quad (16)$$

where $\Phi(k, k_0)$ is the $n \times n$ transition matrix and $H(k, i)$ is the $p \times m$ discrete-impulse (pulse) response:

$$\Phi(k,l) = \begin{cases} A(k-1)\cdots A(l) & k > l, \\ I & k = l, \end{cases} \quad (17)$$

$$H(k,i) = \begin{cases} C(k)\Phi(k,i+1)B(i) & k > i, \\ D(k) & k = i, \\ 0 & k < i. \end{cases}$$
$$(18)$$

In the time-invariant case, Eqs. (15) and (16) become

$$x(k+1) = Ax(k) + Bu(k),$$
$$y(k) = Cx(k) + Du(k), \quad (19)$$

and

$$y(k) = CA^k x_0 + \sum_{i=0}^{k-1} H(k,i)u(i), \quad k > 0,$$
$$(20)$$

where, without loss of generality, k_0 is taken to be zero.

The discrete-impulse (pulse) response is now given by

$$H(k,i) = \begin{cases} CA^{k-(i+1)}B & k > i, \\ D & k = i, \\ 0 & k < i. \end{cases} \quad (21)$$

Since the system is time invariant, $H(k,i) = H(k-i,0)$ and i, the time the pulse input is applied, can be taken to be zero. The transfer function matrix for (19) is the (one-sided or unilateral) z-transform of $H(k,0)$:

$$H(z) = \mathcal{Z}\{H(k,0)\} = C(zI-A)^{-1}B + D. \quad (22)$$

It can be shown that given a $p \times m$ matrix $H(k,i)$, $k \geq i$, it is realizable as the pulse response of a system (15) if and only if $H(k,i)$ can be decomposed as

$$H(k,i) = \begin{cases} M(k)N(i) & k > i, \\ D(k) & k = i. \end{cases} \quad (23)$$

If, in addition, $H(k,i) = H(k-i,0)$, then it is realizable via a time-invariant description (19).

Similarly to the continuous-time case, $H(z)$ is realizable as the transfer function matrix of a system described by (19) if and only if

$$\lim_{z \to \infty} H(z) < \infty. \quad (24)$$

A realization (19) of $H(z)$ is minimal if and only if it is reachable (controllable from the origin) and observable. And if (19) is a minimal realization of $H(z)$, then any other minimal realization is equivalent to (19).

Realization Algorithms

Given a transfer function $H(s)$ (or $H(z)$), we are interested in finding a minimal (irreducible, or of least order) realization of the form (4) (or (19)).

First note that there are methods to determine the order n of a minimal realization directly from $H(s)$ via the characteristic polynomial and notions such as McMillan degree of $H(s)$ or via the Markov parameters of $H(s)$ and the Hankel matrix. This can be done without finding a minimal realization. Knowing the order of a minimal realization in advance is useful as it provides a guide as to what we should expect when we determine an actual realization. Details may be found in the references below.

In special cases, it is possible that the realization algorithm results directly in a controllable and observable and therefore minimal realization. It is more common however for the algorithm to result in just an either controllable or observable realization, in which case an extra step is needed to isolate the uncontrollable, say, part of the realization and take only the part that it is both controllable and observable. The reader should consult any of the references below for detailed descriptions of several realization algorithms.

Here an example is given of a single-input, single-output system where the resulting realization is controllable and observable, therefore minimal.

Example 1

$$H(s) = \frac{b_2 s^2 + b_1 s + b_0}{s^3 + a_2 s^2 + a_1 s + a_0}.$$

$$A = \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ -a_0 & -a_1 & -a_2 \end{bmatrix}, \quad B = \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix},$$

$$C = \begin{bmatrix} b_0, & b_1, & b_2 \end{bmatrix},$$

is controllable ((A, B) have a form called *controller form*) and observable and therefore minimal realization of $H(s)$; note that all cancellations are assumed to have already taken place between numerator and denominator of a transfer function $H(s)$. This algorithm easily generalizes to the case when the degree of the denominator of $H(s)$ is n (in this example it is 3). Note that if $\lim_{s \to \infty} H(s) = D \neq 0$, then apply the previous algorithm to $\hat{H}(s) = H(s) - D$ to obtain A, B, and C.

Summary

The state variable realization of impulse responses and transfer functions was one of the early problems addressed by system theory. Its solution provides clear understanding of the relations between external (input–output) and internal descriptions of systems. A key result is that any minimal order realization is controllable and observable. Many realization algorithms may be found in the literature. Extensions to polynomial matrix descriptions can also be found in the literature, as well as extensions to partial realizations.

Recommended Reading

A clear understanding of the relationship between external and internal descriptions of systems is one of the principal contributions of systems theory. This topic was developed in the early 1960s with original contributions from Gilbert (1963) and Kalman (1963). The role of controllability and observability in minimal realization is due to Kalman (1963); see also Kalman et al. (1969). For extensive historical comments, see Kailath (1980). The time-varying case is treated in Brockett (1970), Antsaklis and Michel (2006), and Rugh (1996).

RTO

Abstract

RTO aims to optimize the operation of the process taking into account economic terms directly. There are several fundamental gears for smooth operating of an RTO solution. The RTO loop is an extension of feedback control system and consists of subsystems for (a) steady-state detection, (b) data reconciliation and measurement validation, (c) process model updating, and (d) model-based optimization followed by solution validation and implementation. There are several alternatives for each one of these subsystems. This contribution introduces some of the currently used approaches and gives some perspectives for future works in this area.

Keywords

Introduction

Effectiveness, efficiency, product quality, process safety, and low environmental impact are the main driving forces for the improvement of the operation of industrial processes. Real-time (or online) optimization (RTO) is one of the options that are available to achieve these goals and is attracting considerable industrial interest due to its direct and indirect benefits.

RTO systems are model-based, closed-loop process control systems whose objective is to maintain the process operation as nearly as possible to the optimal operating point. Such RTO systems use rigorous process models and current economic information to predict the optimal process operating conditions. Additionally, RTO can mitigate and reject long-term disturbances and performance losses (e.g., due to fouling of heat exchangers or deactivation of catalysts).

The direct benefit from applying RTO is improving the economic performance in terms of increasing the profit of the plant and reducing energy consumption and pollutant emissions.

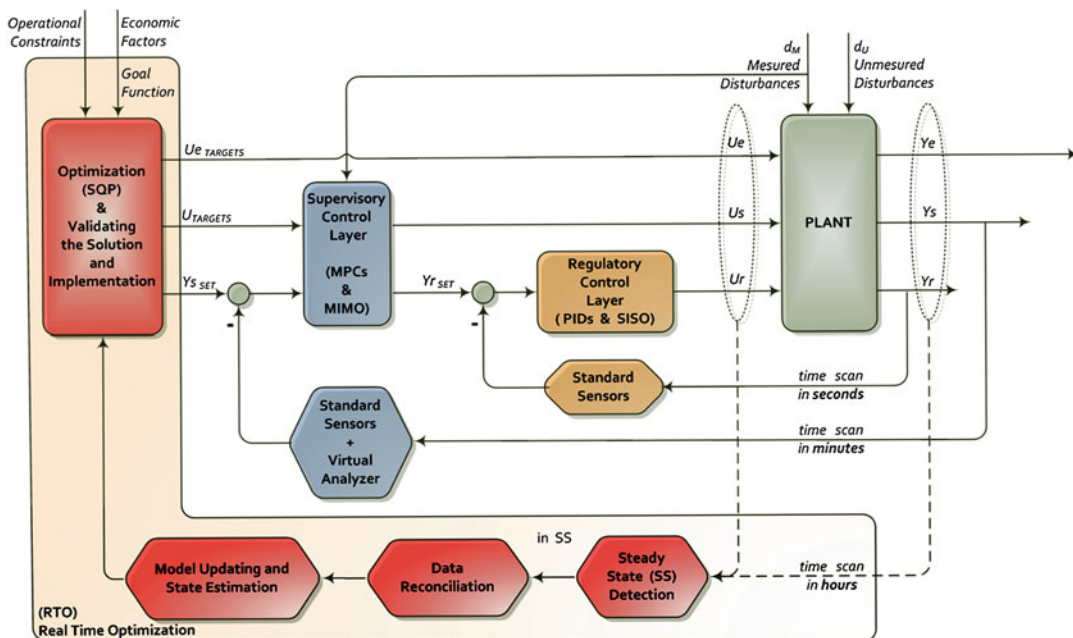
These are also called the *online benefits*. The indirect benefits result from the tools used in the implementation of RTO. For instance, a better understanding of the processes can be employed to debottleneck the plant and to reduce operating difficulties. In addition, abnormal measurement information obtained from gross error detection can help instrumentation and process engineers to troubleshoot the plant instrument errors. Parameter estimation is very useful for process engineers to evaluate the equipment conditions and to identify decreasing efficiencies and other sources of problems. Furthermore, the detailed process simulation of the model used in online optimization can be used for process monitoring and serve as a training tool for new operators. Finally, the rigorous process model can be used for process maintenance, advanced process control, process design, facility planning, and process monitoring.

Real-time optimization (RTO) solutions have been developed since the early 1980s, and nowadays there are many petrochemical and chemical applications, especially in the production of ethylene and propylene in fluid catalytic cracking units (FCCUs) (Darby et al. 2011). Other successful industrial applications are mentioned in Alkaya et al. (2009) with the respective economic returns.

Control Layers and the RTO Concept

Usually the process control is stratified into several layers, which have different response times and control objectives. RTO is located in an intermediate layer that provides the connection between plant scheduling (medium-term planning) and the control system (short-term process performance). In a plant control hierarchy, process disturbances are controlled using process controllers, whereas the RTO system must track changes in the optimum operating conditions caused by low-frequency process changes (e.g., raw material quality and composition, catalyst deactivation).

The typical structure of an RTO system is shown in Fig. 1, which depicts the elements of the closed-loop system. The RTO loop is

R


Real-Time Optimization of Industrial Processes, Fig. 1 Basic structure of the traditional RTO

an extension of the feedback control system and consists of subsystems for (a) steady-state detection, (b) data reconciliation and measurement validation, (c) process model updating, and (d) model-based optimization followed by solution validation and implementation. Once the plant operation has reached a steady state, the plant data ($y = [Ye, Ys, Yr]$) are gathered and validated to detect and correct gross errors in the process measurements, and at the same time the measurements may be reconciled using material and energy balances to ensure that the data set used for model updating is consistent. These validated measurements are used to estimate model parameters (θ) to ensure that the model represents the plant faithfully at the current operating point. Then, the optimum controller set points (Ys_{SET}) and manipulated targets ($U_{TARGETS}$ and $Ue_{TARGETS}$) are calculated using the updated model and are transferred to the advanced process controllers after they have been validated to be effectively applied.

Each layer in Fig. 1 has its own specific tasks as discussed in the following:

1. **Regulatory layer.** This layer is focused on basic (e.g., temperature, flow rate) and inventory (e.g., level and pressure) control ensuring safety and operational stability for the industrial plant. The holdups of vapors and gases are measured by pressure sensors, while the holdups of liquids and solids are measured by level and weighing sensors. In the case of unstable processes, the regulatory layer is also responsible for their stabilization, e.g., by temperature control of industrial reactors. No industrial process can operate without this control layer. The typical operation time scan is in the order of seconds. For its design, typical questions that have to be answered are the following: "How to ensure safe unit operation?" "How to quickly meet the demands coming from the supervisory layer or from the operators?" "How to prevent disturbances to propagate throughout the plant?" The control technology that prevails in this layer is SISO (single-input-single-output) PID controllers, with very few cases where the derivative action is effectively employed. In Fig. 1, Yr are the controlled variables of this

layer (e.g., levels, flow rates, pressures, temperatures, pH), and *Ur* are the corresponding manipulated variables, typically control valves.

2. **Supervisory layer.** This layer is concerned with the quality of the final product. The goal is to ensure the specifications without infringing the operating limits of the equipment. Typically, in this layer there is a strong interaction between the controlled variables, requiring tailored multi-look control structures or the use of multivariate control techniques. The dominant advanced technology in this layer is model predictive control (MPC). In this layer the calculations and updates are performed on the time scale of minutes and the typical associated question is "how to ensure the quality of the final product while satisfying the operating constraints and improving the profitability by reducing the variability of the product parameters?" Here the controlled variables (*Ys*) are usually related to the product quality and the manipulated variables are the set points for the regulatory layer Yr_{SET} and additional manipulated variables (Us) not used by the regulatory layer (e.g., variable frequency drive).

3. **RTO layer.** Here the main focus is the profitability of the process. Specifications and operating points (i.e., set points and targets for the manipulated variables) are determined by solving an optimization problem that aims at maximizing the profitability of the process under stationary conditions. When the optimal operating point is close to the operational limits, the real-time optimization is quite straightforward, since it is enough to take the process to these limits, which is usually done by solving a linear programming (LP) optimization problem. Such simple solutions are effective especially in cases where it is known that to maximize or to minimize the flow rate of a given stream will maximize the profitability. As this kind of solution can be easily implemented, most commercial predictive controllers already have an LP or QP layer integrated, using as a model the gain of the dynamic model used in the MPC. However, for processes with large recycling streams and pronounced nonlinearity, this type of solution is not enough to bring the system to its optimal operating conditions. In this case, it is essential to use a nonlinear optimizer that aims at driving the system to operate in the best operating region. When the industrial process works essentially in steady state, the problem can be solved using stationary models. The solutions offered on the market typically involve the use of a stationary process simulator (e.g., Aspen Plus, PRO II). The RTO sampling times are in the time scale of hours and the questions to be answered are the following: "What is the best way of operation?" "How to increase the profitability of the process?" "How to decrease energy consumption and to increase the process efficiency?"

Four Elements of Classical Real-Time Optimization

A standard RTO solution requires that all four calculation blocks illustrated in Fig. 1 work together smoothly. In fact, each block can be formulated as an optimization problem by itself. Sometimes these optimization problems are combined together. Below the alternative techniques that can be applied to each of these subsystems are discussed.

Steady-State Detection (SSD)

As indicated in Fig. 1, the RTO loop execution begins with the detection of a steady state. Identifying a steady state may be difficult because process variables are noisy and measurements do not settle at a constant value. Being at a steady state can be defined as an acceptable constancy of the measurements over a given period of time. Therefore, tests for stationarity are commonly based on checking the constancy of the measured quantities.

Mejía et al. (2010) compared 6 different approaches to SSD using 5,760 simulated data sets. They concluded that the method based on the estimation of the absolute value of the first and the second derivatives defined by

$$I_{DER} = \left| \widehat{\frac{dy}{dx}} \right| + 10 \left| \widehat{\frac{d^2y}{dt^2}} \right| \qquad (1)$$

gives the best results. Although this idea is quite simple, as being at a steady state means zero derivatives by definition, it has some implementation issues, due to signal noise and outliers. These problems can be reduced by smoothing the plant data using smoothing splines, noncausal Butterworth filters, or wavelet decompositions. The second best compared approach was the local autocorrelation (Mejía et al. 2010) followed by the two statistical nonparametric tests of independence hypothesis proposed by Bebar (2005) and by the method of Cao and Rhinehart (1995).

Data Reconciliation (DR)

Within the mathematical models of industrial processes, the balance equations that result from conservation laws of mass, energy, etc., are the core that cannot be subject to debate. If the measured data do not satisfy the balance equations, this fact must be attributed to measurement errors or to fundamental model inadequacies. Ruling out the latter, as measurement errors are always present, before using the measured data, they should be adjusted to obey the conservation laws and other constraints, e.g., of their ranges. The adjustment using optimization techniques combined with the statistical theory of errors is called data reconciliation. Unfortunately the adjustment of all variables can be greatly affected by "gross errors" in one variable, so such errors must be detected.

The relationship between a measurement of a variable and its true value can be represented by

$$y_m = y + \overbrace{e_r + e_g}^{error} \qquad (2)$$

where y_m and y are the measured and true values, while e_r and e_g are the random and gross errors, respectively. The random errors (e_r) are assumed to be zero mean and normally distributed (Gaussian), since they are the result of the simultaneous effect of several causes. The gross errors (e_g) are caused by large nonrandom events. They can

be subdivided into measurement-related errors, such as malfunctioning sensors (e.g., incorrect calibration, sensor degradation, or damage to the electronics), and processes-related errors, such as process leaks.

In the absence of gross errors, the simplest version of data reconciliation can be stated as a quadratic programming (QP) problem

$$\min_y \frac{1}{2}(y - y_m)^T Q^{-1}(y - y_m) \qquad (3)$$

subject to the linear or linearized constraint related to the process model, written as

$$A \cdot y - c = 0.$$

The covariance matrix (Q), which is usually diagonal, captures the variance of the sensors and is responsible to distribute the errors among the measurements (y_m). The solution of this problem is the reconciled value that for this simple case is given analytically by

$$y = \left[I - QA^T (AQA)^{-1} A \right] y_m + QA^T (AQA^T)^{-1} c.$$

A rigorous formulation of the reconciliation problem is possible even with nonlinear constraints; only the general existence and uniqueness of a solution is not warranted theoretically.

Several statistical tests have been constructed for the detection of gross errors. Some of them are based in the distribution of the constraint residuals, i.e., $r_c = A \cdot y_m - c$, and others are based on the distribution of the estimated error after the reconciliation procedure, i.e., $\hat{e} = y_m - y$. The evaluation of r_c does not require solving previously the associated data reconciliation problem. For a complete discussion and review, see Narasimhan and Jordache (1999) and Sequeira et al. (2002).

Model Updating

A key, yet difficult, decision in model parameter adaptation is to select the parameters that are

adapted. These parameters should be identifiable and represent actual changes in the process, and their adaptation should help to approach the true process optimum. Clearly, the smaller the subset of parameters, the better the confidence in the parameter estimates and the lower the required excitation (also the better the regularization effect). But too few adjustable parameters can lead to misleading models and thus wrong proposals for operational changes.

In general, the parameter estimation and updating are limited not only by the lack of information available from experimental data but also by the correlation between the parameters that are identified. The estimation of correlated parameters leads to a high degree of uncertainty in the model, since different combinations of parameter values lead to the same value of the objective function in the estimation problem.

The selection of the right number of parameters to be identified can be done by the analysis of the sensitivity matrix (S). The elements of S, s_{ij}, are the partial derivatives of the measurement y_i with respect to the parameter θj evaluated at the current value of the parameter (θ_0), i.e.,

$$s_{ij} = \left(\frac{\partial y_i}{\partial \theta_j} \right) \Bigg|_{\theta = \theta_0}. \qquad (4)$$

In general, different parameters and measurements have distinct magnitudes. Therefore, scaling is a key issue that has a strong impact on the results. Traditionally each element of the matrix S is scaled by the initial guess θ_{0j} of the parameter and by the average value of the measurement i ($\overline{y_{si}}$). The scaled elements $s_{s,ij}$ are then given by

$$s_{s,ij} = \left(\frac{\theta_{0j}}{\overline{y_{si}}} \right) \left(\frac{\partial y_i}{\partial \theta_j} \right) \Bigg|_{\theta = \theta_0} \qquad (5)$$

This scaling procedure has some problems, once it requires both a good initial guess for the parameters and representative average values for the measurements. But the main drawback is that it does not consider the multivariable nature existing among all parameters and outputs. To solve these drawbacks, Botelho et al. (2012) proposed

to apply diagonal scaling matrices L and R that result from the solution of the convex optimization problem to find the minimized condition number of the sensitivity matrix, $\gamma(LSR)$, i.e.,

$$\begin{aligned} &\min_{L,R} \gamma(LSR) \\ &s.t. L \in \Re^{ny X ny}, \textit{diagonal and nonsingular} \quad (6) \\ &\quad R \in \Re^{n\theta X n\theta}, \textit{diagonal and nonsingular} \end{aligned}$$

This convex optimization problem can be solved using the LMI (linear matrix inequality) approach as described by Boyd et al. (1994). With the optimized scaling matrices L and R, the scaled sensitivity matrix S_s is given by

$$S_s = LSR \qquad (7)$$

With S_s, the best subset of parameters to be estimated can be determined using the non-square relative gain array matrix (NSRGA) as also proposed by Botelho et al. (2012). The NSRGA can be easily calculated for the scaled sensitivity matrix by

$$NSRGA\,(S_s) \underset{=}{\mathrm{def}} S_s \circ (S_s^\dagger)^T \qquad (8)$$

where $(S_s^\dagger)^T$ is the transpose of the pseudo-inverse of S_s and $\circ$ is the entrywise product (also known as the Hadamard or element-wise product). The rows of $NSRGA\,(S_s)$ are related to the output measurements, whereas the columns are related to the parameters. The sum of the values in each column, whose values can vary between 0 and 1, reflects the relevance of each parameter, and it can be used to sort in descending order their influence on the outputs. When the sum of a column is close to 1, the corresponding parameter has a small correlation with the other ones and a strong influence on the output measurements.

Figure 2 illustrates the typical ordering produced by sorting the $NSRGA\,(S_s)$ in descending order. Thus, it is possible to have an idea of which parameters should be selected for estimation. The values presented in this figure suggest that the parameters $P11$ and $P4$ have very small correlation with the others and should be selected as updated parameters, whereas the parameters $P12$
Real-Time Optimization of Industrial Processes, Fig. 2 Illustrative example of using $NSRGA\,(S_s)$ to rank the parameters

and $P1$ show the opposite behavior and should not be updated.

Solving the Optimization Problem

Nonlinear programs for RTO can be formulated using models of different complexities. For example, RTO can be based on process models similar to those used for design and analysis, using commercial simulators (e.g., Aspen Plus, PRO II, HYSYS, etc.). On the other hand, because these problems need to be solved at regular intervals (at least every few hours), detailed simulation models can be partly replaced by correlations or operating curves that are fitted to the process and updated on a longer time scale.

If a rigorous process model is used, the number of nonlinear equations can be very large. The model is usually built by linking smaller submodels. The optimization problem can be formulated as the following nonlinear programming problem (NLP):

$$\min_{x_M, S_M} f(x_M, S_M)$$
$$s.t.$$
$$M_1(x_{M1}, S_{M1}; \theta_{M1}) = 0$$
$$\vdots$$
$$M_n(x_{Mn}, S_{Mn}; \theta_{Mn}) = 0$$
$$OC(x_M, S_M) \leq 0$$
$$x_M = [x_{M1}, \ldots, x_{Mn}], S_M = [S_{M1}, \ldots, S_{Mn}],$$
$$(9)$$

where M_i are the unit modules that can be solved by a tailored procedure in the modular approach or all together in the equation-oriented approach. Each unit model M_i has internal variables x_{Mi} and parameters θ_{Mi}. These unit models are connected by the input and output streams S_{Mi}. Additionally, there are operating constraints OC to capture the possible lower and upper bounds and other equipment constraints. The objective function $f(x_M, S_M)$ is based on an economic model that involves the raw materials, products, and operating costs.

Successive quadratic programming (SQP) has become the most popular method for solving these nonlinear constrained optimization problems. SQP converges the equality and inequality constraints simultaneously with the optimality conditions. This strategy requires relatively few function evaluations and often performs efficiently for process optimization problems. The NLP solver can be implemented in a nonintrusive way, similar to recycle convergence modules that are already in place. As a result, the structure of the simulation environment and the unit operation blocks does not need to be modified in order to include the optimization, so that SQP can be easily incorporated within existing modular simulators and therefore be applied directly to flow sheets modeled in these commercial simulators. However, in this case derivative

information must be obtained by numerical differentiation which increases the effort and slows down convergence near the optimum.

For fully equation-oriented models with the exact first and second derivatives for all constraints and objective functions, efficient NLP algorithms were developed. For instance, large equation-based models can be solved efficiently with structured barrier NLP solvers (see Biegler 2010 for a detailed overview). But for problems where function evaluations are expensive, and gradients and Hessians are difficult to obtain, it is not clear that large-scale NLP solvers should be applied. Black-box optimization models with inexact (or approximated) derivatives and few decision variables are poorly served by large-scale NLP solvers, and derivative-free optimization algorithms should be considered instead. For the standard RTO problems formulated using modular process simulator model, SQP and reduced-space SQP methods are expected to perform well (see Alkaya et al. 2009; Biegler 2010 for detailed discussion).

After solving the RTO optimization problem, it is necessary to decide if the solution can be implemented. For this, it is necessary to verify if the dominant cause of the plant changes is noise, since in this case implementing these changes could lower the profit. Thus, an important challenge in RTO results analysis is to determine when to implement the calculated changes (Miletic and Marlin 1996).

Summary and Future Directions

RTO aims at optimizing the operation of the process taking into account economic terms directly. There are several fundamental needs for a smooth operation of an RTO solution. The central point is the mathematical modeling which can be a complex first principle model or be based on simple operating curves. If a good model is available, it is necessary to have a good characterization of the inlet streams (properties and composition), to employ data reconciliation and gross error detection and steady-state identification. Finally, the efficiency of the optimizer is a key issue.

Due to the time and resources needed to implement and maintain an RTO solution, a full RTO project involves a certain high risk. Therefore, in cases where simpler and easier approaches can be applied with equivalent economic benefits, they should be used instead. For processes with large recycle streams, it is worthwhile to apply the classical RTO strategy, i.e., the one discussed in the last section. In this case the optimal solution is not trivial, once it is not simply the maximal capacity of the plant. For the cases where the optimal operating constraint is a direct consequence of the operating process capacity, the economic optimization can be easily included in the LP or QP layer implemented usually within a model predictive controller.

In the previous section, the so-called two-step approach, where the measurements are used to refine the process model, which is then used to repeat the optimization, was described. Several RTO schemes have emerged since the development of this two-step approach in the 1970s. Recently, it has been proposed to update the model differently. Instead of adjusting the model parameters, one updates correction terms that are added to the cost and constraint functions of the optimization problem. The technique, labeled as modifier adaptation (RTO-MA), forces the modeled cost and constraints to match the plant values (Gao and Engell 2005; Marchetti et al. 2009). The main advantage of RTO-MA compared to the two-step approach lies in its ability to converge to the true plant optimum, even in the presence of structural plant-model mismatch. RTO-MA is a static optimization method which means that its application to a continuous process requires waiting for reaching the steady state before taking measurements, updating the correction terms, and repeating the numerical optimization. Hence, several iterations are generally required before convergence can be achieved. In contrast, implicit methods, such as self-optimizing control (Skogestad 2000) and NCO tracking (François et al. 2005), propose to adjust the inputs online in a control-inspired manner. Especially simple to be implemented is the "self-optimizing" approach, where a feedback control structure is chosen so that maintaining

some function of the measured variables constant automatically maintains the process near an economically optimal steady state in the presence of disturbances. The problem is posed from a plantwide perspective, since the economics are determined by overall plant behavior.

The classical steady-state RTO has some drawbacks related to its low frequency of execution. It is normally run twice or three times per day and one does not consider the cost of transiting from one operating condition to another. Some plants need to respond to market changes very quickly, like grade changes in polymerization and petroleum process. In these processes, market competition requires the capability to accommodate fast and cost-effective transitions so that companies can produce and sell on demand at favorable prices. To provide this capability, dynamic RTO is being developed and implemented in industrial processes. The largest difference between steady-state and dynamic RTOs is that traditional RTO only provides optimal operating conditions at the steady state, while dynamic RTO provides a trajectory of changes of operating conditions. Dynamic RTO does not require steady-state conditions to be applied. The formulation and solution of the problem DRTO are very similar to the approach used to solve nonlinear predictive controllers (NMPC), with the primary difference the inclusion of economic aspects in the objective function (Engell 2007).

Recommended Reading

As a number of design decisions must be made in the construction of a RTO system, there is no single approach how to implement it. The elements of the solution were discussed here which should be viewed as a starting point for further reading. The review paper by Engell (2007) discusses and compares several approaches for RTO and DRTO giving a quite general and broad perspective of the area. For the reader interested more in the solution and formulation of the optimization problems, the book by Biegler (2010) is a very good starting point and gives a complete discussion about the solvers currently used, illustrating the application with several examples. For data reconciliation and gross error detection the book by Narasimhan and Jordache (1999) is a good starting point. Finally, an industrial discussion about RTO and alternative approaches that have been used in the industry can be found in Darby et al. (2011).

Redundant Robots

Stefano Chiaverini
Dipartimento di Ingegneria Elettrica e dell'Informazione "Maurizio Scarano", Università degli Studi di Cassino e del Lazio Meridionale, Cassino (FR), Italy

Abstract

Redundancy may occur in different ways in a robotic system. This entry focuses on the resolution of kinematic redundancy, i.e., on the techniques for exploiting the redundant degrees of freedom in the solution of the inverse kinematics problem; this is indeed an issue of major relevance for motion planning and control purposes.

Keywords

Introduction

Redundant robots possess more resources than those strictly required to execute their task; this provides the robot with an increased capacity of facing real-world applications by allowing to handle performance issues besides the mere achievement of a given motion trajectory.

Redundancy may occur in the sensory system, in the mechanical structure, and/or in the actuation system, thus allowing, e.g., fault accommodation, multisensory perception, dexterous motion, and load sharing. Nevertheless, unless otherwise specified, by *redundant robot* it is meant one that has a kinematically redundant mechanical structure, i.e., provided with more degrees of freedom than those strictly required to execute its task; this also typically leads to a redundancy in the number of actuators and sensors. Noticeably, *kinematic redundancy* is usually the key to handle the avoidance of singular configurations, the occurrence of joint limits, the engagement of obstacles in the workspace, and the minimization of joint torques or energy. In practice, if properly managed, the increased dexterity characterizing kinematically redundant robots may allow them to achieve a higher degree of autonomy.

In principle, no robot is inherently redundant; rather, there are certain tasks with respect to which it may become redundant. Nevertheless, since most papers in the classical literature on the topic have dealt with robotic manipulators (for which a general task consists in tracking an end-effector motion trajectory requiring six degrees of freedom), a robot arm with seven or more joints is often considered as a typical example of an inherently redundant manipulator. However,

even robot arms with fewer degrees of freedom, like conventional six-joint industrial manipulators, may become kinematically redundant for specific tasks, such as simple end-effector positioning without constraints on the orientation.

In the case of traditional industrial applications involving nonredundant mechanical structures, the occurrence of singular configuration and/or the presence of obstacles in the workcell resulted in the need of a carefully structured (and static) working space where the motion of the manipulator could be planned in advance.

On the other hand, the presence of redundant degrees of freedom allows motions of the manipulator that do not displace the end effector (the so-called self-motions or internal motions); this implies that the same end-effector task can be executed with several different joint motions, giving the possibility of better exploiting the workspace of the manipulator and ultimately resulting in a more versatile robotic arm (see Fig. 1). Such feature is a key to allow operation in unstructured and/or dynamically varying environments that characterize advanced industrial applications and service robotics scenarios.

The biological archetype of a robotic manipulator is the human arm, which, not surprisingly, also inspires the terminology used to characterize the serial-chain structure of a robot *arm*. Remarkably, a simple look at the human arm kinematics from the torso to the hand allows to recognize seven degrees of freedom (three at the *shoulder*,

one at the *elbow*, and three at the *wrist*) that make a manipulator kinematically redundant.

The kinematic arrangement of the human arm has been replicated in a number of robots often termed as *human-armlike manipulators* (see, e.g., Fig. 2). Manipulators with a larger number of joints are often called *hyperredundant robots* and include – among others – snakelike robots (Fig. 3).

The use of two or more robotic structures to execute a task (as in the case of cooperating manipulators or multifingered hands or multiarm/multilegged robots) also gives rise to kinematic redundancy. A headed multilimb structure is typical of a humanoid robot (Fig. 4). Redundant mechanisms also include vehicle-manipulator systems (Fig. 5).

Although the realization of a kinematically redundant structure raises a number of issues from the point of view of mechanical design, this entry focuses on the techniques for exploiting the redundant degrees of freedom in the solution
Redundant Robots, Fig. 1 A self-motion of the arm that keeps the end-effector positioned at the *blue* spot. It is possible to choose configurations that both take the *blue* spot and avoid the *red* obstacle

of the inverse kinematics problem. This is an issue of major relevance for motion planning and control purposes.

Task-Oriented Kinematics

The relationship between the N variables representing the configuration q of an articulated manipulator in the *joint space* and the M variables describing an assigned task t in an appropriate *task space* constitutes a task-oriented kinematics; this can be established at the position, velocity, or acceleration level. Typically, one has $N \geq M$, so that the joints can provide at least the degrees of freedom required for the end-effector task. If $N > M$ strictly, the manipulator is *kinematically redundant*.

At the position level, the *direct kinematics* equation takes on the form

$$t = k_t(q), \tag{1}$$

where k_t is a nonlinear vector function.

Besides the direct kinematics expressed at the position level, it is useful to consider the *first-order differential kinematics* (Whitney 1969)

$$\dot{t} = J_t(q)\,\dot{q}, \tag{2}$$

that can be obtained by differentiating Eq. (1) w.r.t. time. In (2), the mapping between the task-space and the joint-space velocities is held by the $M \times N$ *task Jacobian* matrix $J_t(q) = \partial k_t / \partial q$ (also called *analytic Jacobian*).

Remarkably, $\dot{t}$ expresses the rate of change of the variables adopted to describe the task and thus does not necessarily have the meaning of an end-effector velocity. In general, by denoting the end-effector spatial velocity v_N as the stack of the 3D

translational and angular end-effector velocities, the following relationship holds

$$\dot{\boldsymbol{t}} = \boldsymbol{T}(t)\,\boldsymbol{v}_N\,, \qquad (3)$$

where $\boldsymbol{T}$ is an $M \times 6$ transformation matrix.

For a given manipulator, the mapping

$$\boldsymbol{v}_N = \boldsymbol{J}(\boldsymbol{q})\,\dot{\boldsymbol{q}} \qquad (4)$$

relates a joint-space velocity to the corresponding end-effector velocity through the $6 \times N$ *geometric Jacobian* matrix $\boldsymbol{J}$.

By comparing (2)–(4), the relation between the geometric Jacobian and the task Jacobian can be found as

$$\boldsymbol{J}_\text{t}(\boldsymbol{q}) = \boldsymbol{T}(t)\,\boldsymbol{J}(\boldsymbol{q})\,. \qquad (5)$$

Further differentiation of (2) w.r.t. time provides the following relationship between the acceleration variables:

$$\ddot{\boldsymbol{t}} = \boldsymbol{J}_\text{t}(\boldsymbol{q})\ddot{\boldsymbol{q}} + \dot{\boldsymbol{J}}_\text{t}(\boldsymbol{q},\dot{\boldsymbol{q}})\dot{\boldsymbol{q}}\,. \qquad (6)$$

This equation is also known as *second-order differential kinematics*.

Singularities

A robot configuration $\boldsymbol{q}$ is *singular* if the task Jacobian matrix is rank deficient at it. Considering the role of $\boldsymbol{J}_\text{t}$ in (2) and (6), it is easy to realize that at a singular configuration, it is impossible to generate end-effector task velocities or accelerations in certain directions. Further insight can be gained by looking at (5), which indicates that a singularity may be due to a loss of rank of the transformation matrix $\boldsymbol{T}$ and/or of the geometric Jacobian matrix $\boldsymbol{J}$.

Rank deficiencies of $\boldsymbol{T}$ are only related to the mathematical relationship between $\boldsymbol{v}_N$ and $\boldsymbol{t}$, $\dot{\boldsymbol{t}}$; for this reason, a configuration at which $\boldsymbol{T}$ is singular is referred to as a *representation singularity*. A representation singularity is not directly related to the true motion capabilities of the manipulator structure, which can be instead inferred by the analysis of the geometric Jacobian matrix. Rank deficiencies of $\boldsymbol{J}$ are in fact related to loss of mobility of the manipulator end effector; indeed, end-effector velocities exist in this case that are unfeasible for any velocity commanded at the joints. A configuration at which $\boldsymbol{J}$ is singular is referred to as a *kinematic singularity*.

Since redundancy resolution methods involve the inversion of the task differential kinematics (2) and (6), the handling of singularities through proper treatment of the Jacobian matrix is very important. However, due to space limitations, this topic is out of the scope of this entry and in the following, we will assume that the Jacobian matrices at issue are all full rank.

Null-Space Velocities

With a full-rank task Jacobian, at each configuration an $N - M$ dimensional null space of $\boldsymbol{J}_\text{t}$ exists made of the set of joint-space velocities that yield zero task velocity; these are thus called *null-space velocities* in short.

Remarkably, the components of $\dot{\boldsymbol{q}}$ in the null-space of $\boldsymbol{J}_\text{t}$ produce a change in the configuration of the manipulator without affecting its task velocity. This can be exploited to achieve additional goals – like obstacle or singularity avoidance – in addition to the realization of a desired task motion and constitutes the core of redundancy resolution approaches.

Inverse Differential Kinematics

The inverse kinematics problem can be solved by inverting the direct kinematics equation (1), the first-order differential kinematics (2) or the second-order differential kinematics (6). With a time-varying desired task reference, it is convenient to solve the differential kinematic relationships because these represent linear equations with the task Jacobian as the coefficient matrix.

For a kinematically redundant manipulator, the general solution of (2) or (6) can be expressed by resorting to the pseudoinverse $\boldsymbol{J}_\text{t}^\dagger$ of the task Jacobian matrix (Whitney 1969).

The general solution of (2) can be written as

$$\dot{\boldsymbol{q}} = \boldsymbol{J}_\text{t}^\dagger(\boldsymbol{q})\,\dot{\boldsymbol{t}} + \boldsymbol{N}_{\boldsymbol{J}_\text{t}}(\boldsymbol{q})\,\dot{\boldsymbol{q}}_0\,, \qquad (7)$$

where

$$N_{J_t}(q) = I - J_t^\dagger(q)J_t(q)$$

is an orthogonal projection matrix into the null-space of J_t, and $\dot{q}_0$ is an arbitrary joint-space velocity; the second part of the solution is therefore a null-space velocity. The particular solution obtained by setting $\dot{q}_0 = 0$ in (7) is known as the *pseudoinverse solution*.

As for the second-order kinematics (6), its solution can be expressed in the general form

$$\ddot{q} = J_t^\dagger(q)(\ddot{t} - \dot{J}_t(q,\dot{q})\dot{q}) + N_{J_t}(q)\,\ddot{q}_0, \quad (8)$$

where $\ddot{q}_0$ is an arbitrary joint-space acceleration.

In summary, for a kinematically redundant manipulator, the inverse kinematics problem admits an infinite number of solutions, so that a methodology to select one of them is needed.

Redundancy Resolution via Optimization

An approach to redundancy resolution is based on the optimization of suitable performance criteria.

Performance Criteria

The availability of redundant degrees of freedom can be used to improve the value of performance criteria during the motion. These criteria may depend on the robot joint configuration only or involve also velocities and/or accelerations.

The most frequently considered performance objective for trajectory tracking tasks is singularity avoidance. In fact, singularities lead to decreased mobility, and adding kinematic redundancy allows to reduce the extension of the workspace region where the manipulator is necessarily at a singular configuration (*unavoidable* singularities Baillieul et al. 1984). Possible performance criteria to drive the manipulator motion out of avoidable singularities are configuration-dependent functions that characterize the distance from singular configurations, i.e., the manipulability measure,

the condition number, and the smallest singular value of J_t.

Since kinematic inversion produces very high joint velocities in the vicinity of singular configurations, a conceptually different possibility is to minimize the norm of the joint velocity generated by the redundancy resolution scheme.

Redundancy can be also used to keep a robot away from undesired regions of the joint space or of the task space. For example, it might be desired that a manipulator avoids reaching mechanical joint limits (Liégeois 1977). Another interesting application is obstacle avoidance, which can be enforced by minimizing suitable artificial potential functions defined on the basis of the image of the obstacle region in the configuration space.

Many other performance criteria can be found in the literature.

Local Optimization

Equation (7) provides least-squares solutions to the end-effector task constraint (2), so that it minimizes $\|\dot{t} - J\dot{q}\|$.

The simplest form of local optimization is represented by the pseudoinverse solution that provides the joint velocity with the minimum norm among those which realize the task constraint. Clearly, the joint movement generated by this locally optimal solution does not provide global velocity minimization along the entire manipulator motion; therefore, singularity avoidance is not guaranteed (Baillieul et al. 1984).

In terms of the inverse differential kinematics problem, the least-squares property may quantify the accuracy of the end-effector task realization, while the minimum norm property may be relevant for the feasibility of the joint-space velocities.

Another possibility is to use the general solution (7), choosing $\dot{q}_0$ as

$$\dot{q}_0 = -k_H\,\nabla H(q), \quad (9)$$

where k_H is a scalar stepsize and $\nabla H(q)$ denotes the gradient of a scalar configuration-dependent performance criterion H which is desired to minimize (Liégeois 1977).

As for the second-order solution (8), choosing $\ddot{\boldsymbol{q}}_0 = \boldsymbol{0}$ gives the minimum norm acceleration solution.

Global Optimization

Local optimization algorithms can lead to unsatisfactory performance over long-duration tasks. It is therefore natural to consider the possibility of selecting $\dot{\boldsymbol{q}}_0$ in (7) so as to minimize integral criteria of the form

$$\int_{t_i}^{t_f} H(\boldsymbol{q}) \, dt$$

defined over the whole duration of the task. Unfortunately, the solution of these problems (naturally formulated within the Calculus of Variations framework) may not exist and does not admit a closed form in general. One way to make the problem solvable is to use an integral criterion in quadratic form in the joint velocities or accelerations. However, this is more easily done at the second-order kinematic level (see section "Second-Order Redundancy Resolution").

Redundancy Resolution via Task Augmentation

Another approach to redundancy resolution consists in augmenting the task vector so as to tackle additional objectives expressed as constraints.

Extended Jacobian

The extended Jacobian technique (Baillieul 1985) enforces an appropriate number of functional constraints to be fulfilled along with the original end-effector task.

Given an objective function $g(\boldsymbol{q})$, if $\boldsymbol{J}_t$ has full rank a set of $N - M$ independent constraints can be obtained from the equation

$$\left. \frac{\partial g(\boldsymbol{q})}{\partial \boldsymbol{q}} \right|_{\boldsymbol{q} = \widehat{\boldsymbol{q}}} \boldsymbol{N}_{J_t}(\widehat{\boldsymbol{q}}) = \boldsymbol{0}^{\mathrm{T}},$$

where $\widehat{\boldsymbol{q}}$ is the current joint configuration such that the function $g(\boldsymbol{q})$ is at an extreme; these

$N - M$ independent constraints can be written in vector form as

$$\boldsymbol{h}(\widehat{\boldsymbol{q}}) = \boldsymbol{0}.$$

For a motion that tracks a trajectory $\boldsymbol{t}(t)$ by keeping $g(\boldsymbol{q})$ extremized at each time, it is

$$\begin{bmatrix} \boldsymbol{t}(t) \\ \boldsymbol{0} \end{bmatrix} = \begin{bmatrix} \boldsymbol{k}_t\big(\boldsymbol{q}(t)\big) \\ \boldsymbol{h}\big(\boldsymbol{q}(t)\big) \end{bmatrix},$$

that, similarly to (1) and (2), leads to define an *extended Jacobian* matrix as

$$\boldsymbol{J}_{\mathrm{ext}}(\boldsymbol{q}) = \begin{bmatrix} \boldsymbol{J}_t(\boldsymbol{q}) \\ \dfrac{\partial \boldsymbol{h}(\boldsymbol{q})}{\partial \boldsymbol{q}} \end{bmatrix}.$$

Therefore, if the initial joint configuration extremizes $g(\boldsymbol{q})$ and provided that $\boldsymbol{J}_{\mathrm{ext}}$ does not become singular, the time integral of the inverse mapping

$$\dot{\boldsymbol{q}} = \boldsymbol{J}_{\mathrm{ext}}^{-1}(\boldsymbol{q}) \begin{bmatrix} \dot{\boldsymbol{t}} \\ 0 \end{bmatrix} \tag{10}$$

tracks the assigned end-effector trajectory $\boldsymbol{t}(t)$ propagating joint configurations that extremize $g(\boldsymbol{q})$.

The extended Jacobian method has a major advantage over the pseudoinverse solution in that it is *cyclic*, i.e., it generates repetitive joint motion from a repetitive task motion. Moreover, solution (10) can be made equivalent to (7) via suitable choice of the vector $\dot{\boldsymbol{q}}_0$ (Baillieul 1985).

Augmented Jacobian

The task-space augmentation approach is based on the direct definition of a constraint task to be fulfilled along with the end-effector task (Sciavicco and Siciliano 1988).

In detail, let $\boldsymbol{t}_c$ collect P variables that describe the additional tasks to be fulfilled besides the end-effector task $\boldsymbol{t}$. In the general case, it is $P \leq N - M$ although full redundancy exploitation suggests to consider exactly $P = N - M$.

The relation between the joint-space and the *constraint-task* coordinates can be considered as a direct kinematics equation

$$t_c = k_c(q),$$

where k_c is a continuous nonlinear vector function. At this point, an *augmented task* can be defined by stacking the end-effector task with the constraint task as

$$t_a = \begin{bmatrix} t \\ t_c \end{bmatrix} = \begin{bmatrix} k_t(q) \\ k_c(q) \end{bmatrix}.$$

According to this definition, finding a joint configuration q that brings t_a at some desired value means to satisfy both the end effector and the constraint task at the same time.

A solution to this problem can be found at the differential level by inverting the mapping

$$\dot{t}_a = J_a(q)\,\dot{q} \qquad (11)$$

where the matrix

$$J_a(q) = \begin{bmatrix} J_t(q) \\ J_c(q) \end{bmatrix}$$

is termed *augmented Jacobian* and $J_c(q) = \partial k_c / \partial q$ is the $P \times N$ *constraint-task Jacobian* matrix.

A particular choice for the constraint-task vector is $t_c = h(q)$, with h defined as explained in section "Extended Jacobian", that allows the augmented Jacobian method to embed the extended Jacobian one.

Algorithmic Singularities

The specification of additional goals besides tracking the end-effector task raises the possibility that configurations exist at which the augmented kinematics problem is singular while the sole end-effector task kinematics is not; these configurations are termed *algorithmic singularities* (Baillieul 1985). With reference to the velocity mappings (10) and (11), an algorithmically singular configuration is one at which the extended and the augmented Jacobians, respectively, are singular while J_t is full rank.

Remarkably, algorithmic singularities arise from the way in which the constraint task conflicts with the end-effector task and are not

a problem of the specific inverse kinematic technique (Baillieul 1985). This is easily understandable in simple situations such as that of a desired trajectory passing through an obstacle, where either the trajectory is tracked or the obstacle is avoided, so that both tasks cannot be achieved together. If the origin of the conflict between the two tasks has a clear meaning, the algorithmic singularity may be avoided by keenly specifying the constraint task case-by-case; otherwise, analytical tools must be adopted.

Task Priority

Conflicts between the end-effector task and the constraint task are handled in the framework of the task-priority strategy by suitably assigning an order of priority to the given tasks and then satisfying the lower-priority task only in the null-space of the higher-priority task (Maciejewski and Klein 1985; Nakamura et al. 1987). The idea is that, when an exact solution does not exist, the reconstruction error should only affect the lower-priority task.

With reference to solution (7), the task-priority method consist in computing $\dot{q}_0$ so as to suitably achieve the P-dimensional constraint-task velocity $\dot{t}_c$. Remarkably, the projection of $\dot{q}_0$ onto the null-space of J_t ensures lower priority of the constraint task with respect to the end-effector task since it results in a null-space velocity for the end-effector task.

Consistently with the defined order of priority between the two tasks, a reasonable choice is then to guarantee exact tracking of the primary-task velocity while minimizing the constraint-task velocity reconstruction error $\dot{t}_c - J_c\dot{q}$; this gives (Maciejewski and Klein 1985)

$$\dot{q} = J_t^{\dagger}(q)\dot{t} + \left(J_c(q)N_{J_t}(q)\right)^{\dagger}\left(\dot{t}_c - J_c(q)J_t^{\dagger}(q)\dot{t}\right). \qquad (12)$$

It can be recognized that the problem of algorithmic singularities still remains; in fact, the matrix $J_c \cdot N_{J_t}$ may lose rank with full-rank J_t and J_c. However, differently from the task-space augmentation approach, correct primary-task solutions are expected as long as the sole

primary-task Jacobian matrix is full rank. On the other hand, out of the algorithmic singularities, the task-priority strategy gives the same solution as the task-space augmentation approach; this implies that close to an algorithmic singularity, the solution becomes ill-conditioned and large joint velocities may result.

Another approach is to relax minimization of the secondary-task velocity reconstruction constraint and simply pursue tracking of the components of $J_{\mathrm{c}}^{\dagger}\dot{t}_{\mathrm{c}}$ that do not conflict with the primary task (Chiaverini 1997), namely,

$$\dot{q} = J_{\mathrm{t}}^{\dagger}(q)\dot{t} + N_{J_{\mathrm{t}}}(q)J_{\mathrm{c}}^{\dagger}(q)\dot{t}_{\mathrm{c}}. \qquad (13)$$

A nice property of solution (13) is that algorithmic singularities are decoupled from the singularities of J_{c}.

Second-Order Redundancy Resolution

Redundancy resolution at the acceleration level allows the consideration of dynamic performance along the manipulator motion. Moreover, the obtained acceleration profiles (together with the corresponding positions and velocities) can be directly used as reference signals of task-space dynamic controllers.

The simplest scheme operating at the acceleration level is represented by (8) with $\ddot{q} = 0$. Similar to the velocity-level pseudoinverse solution, the joint motion generated by this locally optimal solution does not result in global acceleration minimization. Remarkably, provided that the appropriate boundary conditions are satisfied, this solution leads to the minimization of the integral of $\dot{q}^{\mathrm{T}}\dot{q}$ (Kazerounian and Wang 1988).

More flexibility in the choice of performance criteria is obviously obtained by considering the full second-order solution (8). Let the manipulator dynamic model be expressed as

$$\tau = H(q)\ddot{q} + c(q,\dot{q}) + \tau_g(q),$$

where τ is the vector of actuator torques, H is the manipulator inertia matrix, c is the vector of

centrifugal/Coriolis terms, and τ_g is the gravitational torque vector. Choosing the null-space acceleration in (8) as

$$\ddot{q}_0 = -\big(H(q)N_{J_{\mathrm{t}}}(q)\big)^{\dagger}$$
$$\cdot\Big(H(q)J_{\mathrm{t}}^{\dagger}(q)\big(\ddot{t}-\dot{J}_{\mathrm{t}}(q,\dot{q})\dot{q}\big)+c(q,\dot{q})+\tau_g(q)\Big)$$

leads to the local minimization of the actuator torque norm $\tau^{\mathrm{T}}\tau$ (Hollerbach and Suh 1987).

Another interesting inverse solution, which minimizes the integral of the manipulator kinetic energy, is the following Kazerounian and Wang (1988):

$$\ddot{q} = J_{\mathrm{t},H}^{\dagger}(q)\big(\ddot{t} - \dot{J}_{\mathrm{t}}(q,\dot{q})\dot{q}\big)$$
$$+ \big(I - J_{\mathrm{t},H}^{\dagger}(q)J_{\mathrm{t}}(q)\big)H^{-1}(q)c(q,\dot{q}),$$

where the *inertia-weighted task Jacobian pseudoinverse* can be computed as

$$J_{\mathrm{t},H}^{\dagger}(q) = H^{-1}(q)\,J_{\mathrm{t}}^{\mathrm{T}}(q)$$
$$\Big(J_{\mathrm{t}}(q)\,H^{-1}(q)\,J_{\mathrm{t}}^{\mathrm{T}}(q)\Big)^{-1}.$$

Once again, the correct boundary conditions must be used.

Summary and Future Directions

To discuss kinematic redundancy, the concept of task-oriented kinematics has been first recalled with the basic methods for its inversion at the velocity and acceleration level. Next, different methods to solve kinematic redundancy at the velocity level have been arranged in two main categories, namely, those based on the optimization of suitable performance criteria and those relying on the augmentation of the task space. Finally, redundancy resolution methods at the acceleration level have been considered in order to take into account dynamics issues, e.g., torque or kinetic energy minimization.

Besides the classical linear algebra methods and optimization tools still ever under investigation, new methodological approaches to

Redundant Robots, Fig. 6 The DLR rolling justin

redundancy resolution recently include learning algorithms (Rolf et al. 2010) and soft computing techniques (Liu and Li 2006). Active fields of new applications are in sensorial redundancy for data fusion (Luo and Chang 2012) and in systems (like the one in Fig. 6) with a large number of degrees of freedom, namely, hyperredundant robots (Salvietti et al. 2009), humanoids (Kanoun and Laumond 2010), and multirobot systems (Antonelli et al. 2010).

Recommended Reading

Because of space and scope limitations, in drawing on overview of such a mature and well-developed topic, there are a number of techniques

and details that go neglected in any case; a slightly more extensive treatment of kinematic redundancy, including a touch on singularity robustness, cyclicity, and hyperredundant manipulators with related first-reading bibliography can be found in Chiaverini et al. (2008). Other major issues of interest that could not be covered here are in the use of kinematic redundancy for fault tolerance, for improved grasping, and for motion/force control; see, e.g., Roberts et al. (2008), Prats et al. (2011), and Khatib (1990), respectively.

Regulation and Tracking of Nonlinear Systems

Lorenzo Marconi
C.A.SY. Ű- DEI, University of Bologna, Bologna, Italy

Abstract

A classical problem in control theory is the design of feedback laws such that the effect of exogenous inputs on selected output variables is asymptotically rejected. This includes problems of asymptotic tracking and disturbance rejection. In this entry, the fundamentals of the theory are presented, as well as constructive procedures for the design of a controller, which embeds an "internal model" of the generator of the exogenous inputs. Current and future research directions are also discussed.

Keywords

Introduction

The problem of controlling a dynamical systems in such way that a "regulated" output tracks reference signals or rejects exogenous disturbances is ubiquitous in control theory. Among various possible different approaches to the solution of this problem, in this entry we present the so-called theory of nonlinear output regulation. A distinctive feature of this theory is that reference/disturbance signals to be tracked/rejected are thought of as unknown functions of time, which belong to the set of all trajectories generated by an autonomous nonlinear system (the so-called *exosystem*). Fundamental in this setting is the concept of *internal model*, developed in the early 1970s for linear systems by Francis and Wonham (1976) and subsequently extended, beginning with the work (Isidori and Byrnes 1990), to the case nonlinear systems. Since these early contributions, nonlinear output regulation has been an active research domain, in which constant improvements have brought the theory to a stage of full maturity. In this entry we introduce the fundamental principles of the nonlinear output regulation theory and the associated design tools. The entry ends with an overview of actual research trends and future research directions.

The Generalized Tracking Problem for Nonlinear Systems

We consider the class of time-invariant smooth nonlinear systems described in the form

$$\begin{aligned} \dot{x} &= f(w, x, u) \\ e &= h(w, x) \\ y &= k(w, x) \end{aligned} \qquad (1)$$

in which $x \in \mathbb{R}^n$ is the state, $u \in \mathbb{R}^m$ is the control input, $y \in \mathbb{R}^q$ is the measured output, and

$e \in \mathbb{R}^p$ is the regulation *error*. The input $w \in \mathbb{R}^s$ models exogenous signals that might represent references to be tracked, exogenous disturbances to be rejected, or also parametric uncertainties. In this framework the problem is to design a controller of the form

$$\begin{aligned}\dot{\xi} &= \varphi(\xi, y) \qquad \xi \in \mathbb{R}^\nu \\ u &= \gamma(\xi, y)\end{aligned} \qquad (2)$$

such that the associated closed-loop system (1)–(2) has bounded trajectories $(x(t), \xi(t))$ and the resulting error $e(t) = h(w(t), x(t))$ is asymptotically vanishing, i.e., $\lim_{t\to\infty} e(t) = 0$. The previous framework encompasses several standard control problems, such as the problem in which a system of the form $\dot{x} = f(x, u)$, with measured output $y = k(x)$ and regulated output $y_r = h_r(x)$, must be controlled in such a way that $y_r(t)$ asymptotically tracks a reference signal $y^*(t)$. This is the case, in fact, if we set $w(t) = y^*(t)$, define $e = h(w, x) = w - h_r(x)$, and drop the dependence from w in the functions $f(\cdot)$ and $k(\cdot)$ in (1). Similarly, the previous framework lends itself to capture a scenario of disturbance suppression, in which, in a system of the form $\dot{x} = f(d, x, u)$, with measured output $y = k(x)$ and regulated output $y_r = h(x)$, the effect of a disturbance $d(t)$ on the regulated output $y_r(t)$ must be asymptotically rejected. This is the case if we set $w(t) = d(t)$ and drop the dependence on w in $h(\cdot)$ and $k(\cdot)$ in (1). Similarly, by letting $h(x) = x$ and interpreting the variable w as parametric uncertainty, the previous setting captures the problem of robust output feedback stabilization, at the origin, of an uncertain system of the form $\dot{x} = f(w, x, u)$ with measured output $y = k(w, x)$. Of course, the general case of tracking reference signals in presence of exogenous disturbances can be cast in a similar manner.

The ability of solving the problem in question strongly depends on the amount of knowledge one assumes about the exogenous variable w in the design of the controller (2). Among the different options available, in this entry we present the so-called theory of output regulation, in which the exogenous variable is assumed to be an *un-*

known member of a *known family* of functions of time. Specifically, it is assumed that $w(t)$ is an unspecified member of the set of all trajectories generated by an autonomous nonlinear system of the form

$$\dot{w} = s(w) \qquad (3)$$

as its initial condition $w(0)$ ranges on a prescribed set $W \subset \mathbb{R}^s$. In this framework, system (3), usually referred to as the "exosystem," is assumed to be known and its knowledge potentially exploitable in the design of (2). The specific "member" $w(t)$ of the family, however, is unspecified as the initial condition $w(0)$ is not known. The fact of regarding $w(t)$ as unknown member of a known family seems to be the right trade-off between the favorable but unrealistic situation in which $w(t)$ is assumed to be perfectly known and the opposite realistic but conservative situation in which $w(t)$ is regarded as a totally unknown signal. An elementary, and yet meaningful, example is given by the case in which $w(t)$ belongs to the family of periodic functions of time with an unspecified frequency, phase, and amplitude. In this case the exosystem (3) is a *nonlinear* system of the form ($w \in \mathbb{R}^3$)

$$\dot{w}_1 = w_2 \qquad \dot{w}_2 = -w_3^2 w_1 \qquad \dot{w}_3 = 0.$$

Solutions of the previous system, in fact, are periodic functions, with frequency $w_3(t) \equiv w_3(0)$ and amplitude and phase depending on the specific initial condition $(w_1(0), w_2(0))$. Other situations, such as exosystems modeling nonlinear oscillators, can be dealt with in a similar fashion.

In the previous context, the problem of output regulation can be formally cast as follows. Let $X \subset \mathbb{R}^n$ be a set of initial conditions for (1). Then, the problem consists in finding a controller of the form (2), with initial conditions in a set $\Xi \subset \mathbb{R}^\nu$, such that the trajectories of the closed-loop system (1)–(2) augmented with (3), originating from an initial condition $(w(0), x(0), \xi(0)) \in W \times X \times \Xi$, are bounded and $\lim_{t\to\infty} e(t) = 0$ *uniformly* in the initial conditions (The property of "uniformity" is relevant in the context of output regulation. It reflects the requirement that the time needed for the error $e(t)$ to reach an

R

ϵ-neighborhood of the origin only depends on the set $W \times X \times -i$, where the initial conditions are supposed to range, and on ϵ but not on the particular value of the initial condition within $W \times X \times \varXi$.). Depending on the assumptions on the set X where the initial conditions of the plant are assumed to range, the problem is further classified in *semiglobal output regulation*, if the set X is a known *compact* but otherwise arbitrary set of $\mathbb{R}^n$, or *global output regulation* if $X = \mathbb{R}^n$.

Output Regulation Principles

Steady State for Nonlinear Systems and Internal Model Principle

Since the objective is to design the controller such that the effect of the exogenous variable is *asymptotically* rejected by the regulation error, it is apparent that any approach to the solution of the problem of output regulation must be necessarily grounded on a precise characterization of the notion of "steady state" for a nonlinear system. As it is the case for the familiar version of this concept in linear systems theory, a notion of "steady state," for the system consisting of (1)–(3), should be able to capture the "limiting behavior" – if any – that such system asymptotically approaches when the "transient behavior," due to the effect of specific initial conditions of plant and controller, fades out and a "persistent behavior," induced only by the specific exogenous input, emerges. In this respect, the mathematical tool that has been shown to be at the core of a rigorous notion of steady state for nonlinear systems is the one of *ω-limit set of a set*. We refer the reader to Hale et al. (2002) for a definition of this notion and to Byrnes and Isidori (2003) for a description of its use in the characterization of the steady-state behavior of a nonlinear system. In this entry, we simply observe that if the trajectories of the system (3)–(1)–(2) that originate from the set of initial conditions $W \times X \times \varXi$ are bounded (which, in turn, is one of the requirements of the problem in question), then there exists a compact set $\mathcal{A} \subset \mathbb{R}^s \times \mathbb{R}^n \times \mathbb{R}^\nu$, which is precisely the ω-limit set of the set $W \times X \times \varXi$ under the dynamics of (3)–(1)–(2), that is *invariant* for the closed-loop system

and that *uniformly* attracts its trajectories. The set $\mathcal{A}$ is usually referred to as *steady-state locus*, while the restriction of the closed-loop dynamics to the set $\mathcal{A}$ are the *steady-state dynamics* of the closed-loop system. The latter characterize the "limiting behavior" of the system towards which all the closed-loop trajectories converge to. Unlike the case of linear systems, though, in a nonlinear context we cannot expect, in general, that the steady-state behavior is only governed by the exogenous w, namely, that the asymptotic behavior of the closed-loop system is totally independent of the initial conditions of the plant and of the regulator. Assuming that the set W is compact and invariant for (3), it can be proven (see Isidori and Byrnes 2008) that the set $\mathcal{A}$ is the graph of a *set-valued* map defined on W, namely, that there exists a map $\sigma : W \to \mathbb{R}^n \times \mathbb{R}^\nu$, which is set-valued in general, such that

$$\mathcal{A} = \{(w, x, \xi) \in W \times \mathbb{R}^n \times \mathbb{R}^\nu \ : \ (x, \xi) \in \sigma(w)\}.$$

Clearly the steady-state locus and the associated steady-state dynamics of the closed-loop system depend on the design of the controller (2). The role of the latter is not only to enforce the existence of a steady state, which is equivalent to enforce bounded closed-loop trajectories, but also to guarantee that the error converges asymptotically to zero uniformly in the initial conditions. In this respect, by bearing in mind the asymptotic properties of the set $\mathcal{A}$, it can be seen that a sufficient condition under which a regulator of the form (2) solves the problem of output regulation is that the steady-state locus is "shaped" in such a way that the regulation error is zero on it, namely,

$$\mathcal{A} \subset \{(w, x, \xi) \ : \ h(w, x) = 0\}. \qquad (4)$$

In fact, it can be proved that condition (4) is not only sufficient but also necessary (see Byrnes and Isidori 2003) as a consequence of the requirement that the error converges to zero uniformly in the initial conditions. That is, any regulator that solves the problem in question necessarily enforces a steady state such that the steady-state locus fulfills (4).

In view of the previous considerations, a crucial property required to any regulator is to induce a steady-state locus $\mathcal{A}$ fulfilling (4). This key feature can be further elaborated by highlighting two necessary conditions, involving separately the plant and the regulator, leading to the notions of *regulator equations* and *internal model property*. To this purpose, consider the simplified, yet relevant, case in which the map $\sigma(\cdot)$ is single-valued and smooth, and let $\pi(w)$ and $\tau(w)$ be the two components of $\sigma(w)$ associated to x and ξ, respectively. By letting

$$c(w) = \gamma(\tau(w), k(w, \pi(w))) \qquad (5)$$

it is immediately realized that the fact that $\mathcal{A}$ is invariant for (1)–(3) implies that the functions $\pi(\cdot)$ and $\tau(\cdot)$ necessarily fulfill

$$\frac{\partial \pi(w)}{\partial w} s(w) = f(w, \pi(w), c(w)) \qquad (6)$$

and

$$\frac{\partial \tau(w)}{\partial w} s(w) = \varphi(\tau(w), k(w, \pi(w))) \qquad (7)$$

for all $w \in W$. Furthermore, the fact that e must be zero on $\mathcal{A}$ (see (4)) implies that necessarily

$$h(w, \pi(w)) = 0 \qquad (8)$$

for all $w \in W$. Equations (6) and (8), interpreted as equations in the unknown $\pi(w)$ and $c(w)$, involve only the regulated plant (1) and are known as *regulator equations* (see Isidori 1995; Isidori and Byrnes 1990). The functions $c(w(t))$ and $\pi(w(t))$, with $w(t)$ solution of (3), represent, respectively, the desired steady-state control input and state towards which the actual control input u and state x of (1) should converge in order to have the regulation goal fulfilled. On the other hand, Eqs. (5) and (7), interpreted as equations in the unknown $\tau(w)$, point out the so-called internal model property required to any regulator solving the output regulation problem, that is, the ability of the regulator to reproduce the ideal steady-state input $c(w(t))$, for all possible $w(t)$ solution of (3), once it is driven by the measured output of

the plant in the ideal steady state (namely, by the function $k(w(t), \pi(w(t)))$). In fact, this property can be achieved by incorporating in the controller an appropriate "internal model" of the exogenous dynamics (3).

Regulator Design

As emphasized in the previous discussion, the design of the regulator involves the fulfillment of two crucial properties. The first is the internal model property, namely, the ability of generating, by means of the regulator outputs, all possible "feedforward inputs" which force an identically zero regulation error and, in turn, to guarantee the existence of an invariant steady-state set on which the error is identically zero. The second property asks that such a steady-state set is asymptotically stable for the closed-loop system with a domain of attraction including the set of initial conditions. A systematic design procedure of regulators simultaneously fulfilling the previous two properties can be found under sufficient conditions that essentially restrict the class of regulated plants (1). In particular, in the following, we consider the class of single input-single output systems that are affine in the input u, with a measurable error variable (i.e., $e = y$) and that after an appropriate change of coordinates can be written in the form

$$\begin{aligned} \dot{z} &= f_z(w, z, e) & z &\in \mathbb{R}^{n-1} \\ \dot{e} &= a(w, z, e) + b(w, z, e)u & e, u &\in \mathbb{R} \end{aligned} \qquad (9)$$

with $f_z(\cdot, \cdot, \cdot)$, $a(\cdot, \cdot, \cdot)$, and $b(\cdot, \cdot, \cdot)$ smooth functions with $b(w, z, e) \neq 0$ for all (w, z, e). Systems of this kind possess a well-defined unitary relative degree (The restriction to systems with unitary relative degree is just made for sake of simplicity. Higher relative degree can be equally dealt with, Isidori (1995).) between the input u and the output e, and the Eqs. (9) are said to be in *normal form* (see Isidori 1995, 2013). In these coordinates an easy calculation shows that the solution of the regulator Eqs. (6) and (8) takes the form $\pi(w) = (\pi_z(w), 0)$, where $\pi_z(\cdot) : W \to \mathbb{R}^{n-1}$ is a solution of

R

$$\frac{\partial \pi_z(w)}{\partial w} s(w) = f_z(w, \pi_z(w), 0),$$

and

$$c(w) = -\frac{a(w, \pi_z(w), 0)}{b(w, \pi_z(w), 0)}.$$

In addition, we further restrict the class of systems by asking for a minimum-phase property (Isidori 1995, 2013). In the present context, the property in question amounts to asking that the set $\mathcal{B} = \{(w, z) \in W \times \mathbb{R}^{n-1} : z = \pi_z(w)\}$ is *asymptotically stable* for the system

$$\dot{w} = s(w)$$
$$\dot{z} = f_z(w, z, 0)$$

with a domain of attraction containing $W \times Z$, with Z the set where the initial condition of z is expected to range.

Existence of the relative degree and the property of minimum-phase are all what is needed to design a regulator. The regulator takes the form

$$\dot{\xi} = F\xi + G(\gamma(\xi) + \kappa(e)) \quad \xi \in \mathbb{R}^\nu$$
$$u = \gamma(\xi) + \kappa(e) \tag{10}$$

in which (F, G) is a controllable pair and $\gamma(\cdot)$ and $\kappa(\cdot)$ are real-valued functions to be properly designed. In particular, it can be shown (see Marconi et al. 2007) that if ν, the dimension of the regulator is taken sufficiently large relative to the dimension of w (specifically, $\nu \geq 2s + 2$) and if F is any matrix whose eigenvalues have negative real part, there exist a continuously differentiable function $\tau(\cdot)$ and a continuous function $\gamma(\cdot)$ such that

$$\frac{\partial \tau(w)}{\partial w} s(w) = F\tau(w) + Gc(w)$$
$$c(w) = \gamma(\tau(w)) \tag{11}$$

for all $w \in W$. This being the case, it is seen that the regulator (10) fulfills conditions (5)–(7) and therefore has the internal model property, regardless of how $\kappa(\cdot)$ is chosen, provided that $\kappa(0) = 0$. In particular, in the closed-loop system (3), (9), and (10), the invariant set $\mathcal{A} = \{(w, z, e, \xi) \in W \times \mathbb{R}^{n-1} \times \mathbb{R} \times \mathbb{R}^\nu : z = \pi_z(w), e = 0, \xi = \tau(w)\}$ fulfills (4) regardless

of how $\kappa(\cdot)$ is chosen. The function $\kappa(\cdot)$ is a degree of freedom that can be chosen to make the steady-state set $\mathcal{A}$ asymptotically stable. In this respect the minimum-phase assumption and the fact that F is a Hurwitz matrix play a role. In fact, the closed-loop system (3), (9), and (10), interpreted as a system with state (w, z, e), input $\kappa(\cdot)$, and output e, have relative degree one and it is minimum-phase. This fact makes it possible to use standard high-gain arguments to show that there exists a function $\kappa(\cdot)$ such that the set $\mathcal{A}$ is asymptotically stable for the closed-loop systems with a domain of attraction containing any (arbitrarily large) compact set of initial conditions (see Marconi et al. 2007; Teel and Praly 1995).

The delicate part in the procedure illustrated above is the design of the function $\gamma(\cdot)$ that is required to fulfill (11) for a suitable $\tau(\cdot)$. Exact, although hardly implementable in practice, expressions for the function $\gamma(\cdot)$ can be found in Marconi and Praly (2008). More constructive design procedures can be found at the price of restricting the class of systems and exosystems that can be dealt with. Such procedures require that the autonomous dynamical system with "output" u^*

$$\dot{w} = s(w)$$
$$u^* = c(w),$$

namely, the system characterizing all possible ideal steady-state inputs, is "immersed" into a system exhibiting certain structural properties (Loosely speaking, the autonomous system with output Σ is immersed into the autonomous system with output $\tilde{\Sigma}$ if the set of all possible functions of time generated as outputs of Σ is a subset of the set of all possible functions generated as outputs of $\tilde{\Sigma}$.). In this respect a number of alternative solutions have been proposed in literature that differ for the kind of underlying immersion assumption and consequent regulator design procedure. Immersion into a linear known observable system (see Byrnes et al. 1997; Huang and Lin 1994; Khalil 1994; Serrani et al. 2000), immersion into a linear unknown (but linearly parameterized) system (Serrani et al. 2001), immersion into a linear system having a nonlinear output map (Chen and Huang 2004), immersion

into a nonlinear system linearizable by output injection (Delli Priscoli 2004), immersion into a system in canonical observability form Byrnes and Isidori (2004), and immersion into a system in a nonlinear adaptive observability form Delli Priscoli et al. (2006a,b) are a few examples of approaches proposed in literature.

Summary and Future Directions

The theory of output regulation for nonlinear systems is an active area of investigation. Research efforts are, in particular, addressed to the problems of weakening the minimum-phase assumption and of identifying *robust* design procedures, to asymptotically stabilize the steady-state locus, not necessarily based on high-gain principles. Recently, the problem of output regulation for multivariable systems has been also addressed (Isidori and Marconi 2012). In this case a paradigm shift in the design of the regulator and of the stabilizer is expected to deal with the problem in its full generality. Finally, it is worth mentioning that the theory of output regulation and internal model-based design methods are being used for the problem of reaching a consensus between the outputs of a network of nonlinear systems exchanging relative information over a communication graph. In this case it has been proved the necessity of internal model-based regulators (Wieland 2010) and the research activity is now conveyed to identify constructive design strategies for classes of nonlinear systems and network topologies.

Risk-Sensitive Stochastic Control

Hideo Nagai
Osaka University, Osaka, Japan

Abstract

Motivated by understanding "robustness" from the view points of stochastic control, the studies of risk-sensitive control have been developed. The idea was applied to portfolio optimization problems in mathematical finance, from which new kinds of problem on stochastic control, named "large deviation control," have been brought, and currently the studies are in progress.

Keywords

Large deviation control; Mathematical finance; Robustness

Risk-Sensitive Criterion

Risk-sensitive stochastic control has the criterion

$$J(x, 0; T; \gamma) = \frac{1}{\gamma} \log E[e^{\gamma\{\int_0^T f(X_s, u_s)ds + \varphi(X_T)\}}] \tag{1}$$

with $\gamma \neq 0$, where X_t is the state variable process defined by the controlled stochastic differential equation

$$dX_t = \sigma(X_t)dB_t + b(X_t, u_t)dt, \quad X_0 = x \tag{2}$$

with the control parameter process u_t. Here $\sigma(x) : R^N \mapsto R^N \otimes R^d$ and $b(x, u) : R^N \times R^m \mapsto R^N$. When $\gamma \to 0$, the criterion behaves as

$$J(x, 0; T; \gamma) \sim E[\int_0^T f(X_s, u_s)ds + \varphi(X_T)]$$
$$+ \frac{\gamma}{2} \text{Var}[\int_0^T f(X_s, u_s)ds + \varphi(X_T)] + O(\gamma^2).$$

Then, minimizing the criterion with $\gamma > 0$ is considered to be risk averse, while with $\gamma < 0$ it is to be risk seeking. The problem minimizing the classical criterion $E[\int_0^T f(X_s, u_s)ds + \varphi(X_T)]$ corresponds to the case of $\gamma = 0$, which is risk neutral.

When $f(x, u) = \frac{1}{2}x^*Qx + \frac{1}{2}u^*Su$, $\varphi(x) = \frac{1}{2}x^*Ux$, and $b(x, u) = Ax + Cu$, $\sigma(x) \equiv \Sigma$ with constant matrices Q, S, U, A, C, Σ, minimizing the criterion subject to the state variable processes X_t is called a linear exponential quadratic Gaussian (LEQG) control problem, where one may assume Q and U to be nonnegative definite and S positive definite.

H-J-B Equations

The Hamilton-Jacobi-Bellman (H-J-B) equation for the problem minimizing criterion J defined by (1) among the controlled processes governed by (2) is seen to be

$$\begin{cases} \frac{\partial v}{\partial t} + \frac{1}{2}\text{tr}[a(x)D^2v] + H(x, \nabla v) = 0 \\ v(T, x) = \varphi(x), \end{cases} \tag{3}$$

where $a(x) := (a^{ij}(x)) = ((\sigma\sigma^*)^{ij}(x))$ and

$$H(x, p) = \frac{\gamma}{2} p^* a(x) p + \inf_u \{b(x, u)^* p + f(x, u)\}.$$

In an LEQG case, where we assume that Q, U are nonnegative definite and S positive definite, the H-J-B equation has the solution expressed as

$$v(t, x) = \frac{1}{2}x^* P(t)x + G(t),$$

by using the solutions $G(t)$ of ordinary differential equation

$$\dot{G}(t) + \frac{1}{2}\text{tr}[P\Sigma\Sigma^*] = 0, \quad G(T) = 0$$

and $P(t)$ of the Riccati equation

$$\dot{P}(t) + PA + A^*P - P(CS^{-1}C^* - \gamma\Sigma\Sigma^*)$$
$$P + Q = 0$$

with the terminal condition $P(T) = U$, provided that it has a nonnegative definite solution $P(t)$. However, it may occur that the Riccati equation does not have any solution if γ is large. In that case, we say that the risk-sensitive control problem "breaks down." Namely, there is no control which makes the criterion have a finite value. On the other hand, if it has a solution, then the optimal feedback control is seen to be $-S^{-1}C^*P(t)x$ and the optimal diffusion process turns out to be the solution to

$$dX_t = \Sigma dB_t + (AX_t - CS^{-1}C^*X_t)dt, \ X_0 = x.$$

The situation can extend to certain general cases. Under sufficiently general conditions one can say that if H-J-B equation (3) has a solution, then no "breakdown" occurs in the corresponding risk-sensitive stochastic control problem (cf. Bensoussan and Nagai 2000; Bensoussan et al. 1998; Nagai 1996).

The LEQG problems were first investigated in Jacobson (1973), and then a theory of the LEQG control with complete or partial state information is developed in Whittle (1981) and Bensoussan and Van Schuppen (1985). Development of the studies of nonlinear risk-sensitive control can be seen in Bensoussan et al. (1998), Nagai (1996), Fleming and McEneaney (1995), etc.

Singular Limits and H^∞ Control

The large deviation theory of Freidlin-Wentzell applies to the risk-sensitive control problem with the criterion

$$J_\epsilon(x, 0; T) = \frac{\epsilon}{\theta}\log E[e^{\frac{\theta}{\epsilon}\int_0^T\{\frac{1}{2}u_s^*S(X_s)u_s + V(X_s)\}ds}]$$
(4)

and the controlled dynamics

$$dX_t = \sqrt{\epsilon}\sigma(X_t)dB_t + \{b(X_t) + C(X_t)u_t\}dt.$$
(5)

The corresponding H-J-B equation is

$$\begin{cases} \frac{\partial v_\epsilon}{\partial t} + \frac{\epsilon}{2}\text{tr}[a(x)D^2v_\epsilon] + H_0(x, \nabla v_\epsilon) + V = 0 \\ v_\epsilon(T, x) = 0, \end{cases}$$
(6)

$$\begin{aligned} H_0(x, p) &= \frac{\theta}{2}p^*a(x)p + b(x)^*p \\ &\quad + \inf_{u\in R^m}\{u^*C(x)p + \frac{1}{2}u^*S(x)u\} \\ &= b(x)^*p - \frac{1}{2}p^*\{CS^{-1}C(x)^* - \theta a(x)\}p. \end{aligned}$$

By employing viscosity solution theory, we can see that, when sending $\epsilon \to 0$, the solution v_ϵ of (6) converges to the viscosity solution w of the equation

$$\begin{cases} \frac{\partial w}{\partial t} + H_0(x, \nabla w) + V = 0 \\ w(T, x) = 0. \end{cases}$$
(7)

Noting that $H_0(x, p)$ can be regarded as

$$\begin{aligned} H_0(x, p) &= \sup_z\{z^*p - \frac{1}{2\theta}z^*a(x)^{-1}z\} \\ &\quad + \inf_u\{u^*C(x)p + \frac{1}{2}u^*S(x)u\}, \end{aligned}$$

Equation (7) is written as

$$\begin{aligned} &\frac{\partial w}{\partial t} + \sup_z\{z^*Dw - \frac{1}{2\theta}(Dw)^*a(x)^{-1}Dw\} \\ &\quad + \inf_u\{u^*C(x)Dw + \frac{1}{2}u^*S(x)u\} = 0 \\ &w(T, x) = 0. \end{aligned}$$

This equation has a unique viscosity solution under suitable conditions. Further, $w(0, x)$ is characterized as the lower value of the differential game with the criterion

$$I(0, T; z_., u(z_.)) = \int_0^T \Psi(x_s, z_s, u(z_.)_s)ds,$$

$$\Psi(x, z, u) = -\frac{1}{2\theta}z^*a(x)^{-1}z + \frac{1}{2}u^*S(x)u + V(x)$$

and the controlled dynamics

$$dx_s = \{b(x_s) + z_s + C(x_s)u(z_.)_s\}ds, \quad x_0 = x,$$

where z_s is a measurable, R^N-valued function on $[0, T]$ such that $\int_0^T |z_s|^2ds < \infty$ and the set of such $\{z_s\}$ is denoted by $\mathcal{Z}_T$. Further, let $\mathcal{U}$ be the

totality of a measurable, R^m-valued function such that $\int_0^T |u_s|^2 ds < \infty$ and $u(z.)$ be a map defined on $\mathcal{Z}$ with its value on $\mathcal{U}$ such that whenever for each $0 \leq \tau \leq T$ and $z^{(1)}, z^{(2)} \in \mathcal{Z}$, $z^{(1)}(s) = z^{(2)}(s)$, almost everywhere on $0 \leq s \leq \tau$, then $u(z.^{(1)})_s = u(z.^{(2)})_s$, a.e. on $0 \leq s \leq \tau$, and the set of such $u(z.)$ is denoted by Γ_U. Thus, the lower value of the game is defined as

$$w(0, x) = \inf_{u(z.) \in \Gamma_U} \sup_{z. \in \mathcal{Z}} I(0, T; z., u(z.))$$

(cf. Bensoussan and Nagai 1997 and references therein). The differential game is known to be related to H^∞ or Robust control. If θ is large, then H-J-B equation (6) may fail to have a solution (cf. Bensoussan and Nagai 1997, 2000). The size of θ ensuring the existence of solution to (6) is related to the level of robustness which the above differential game concerns (Basar and Bernhard 1991; Bensoussan and Nagai 1997, 2000; Bensoussan et al. 1998; Whittle 1990).

Risk-Sensitive Asset Management

The idea of risk-sensitive control applies to mathematical finance (Bielecki and Pliska 1999; Fleming 1995). Consider a market model with $m + 1$ securities, where the security prices are defined by

$$dS^0(t) = r(X_t)S^0(t)dt,$$

$$dS^i(t) = S^i(t)\{\alpha^i(X_t)dt + \sum_{k=1}^{n+m} \sigma_k^i(X_t)dB_t^k\},$$

$i = 1, \ldots m$, with an $n + m$ dimensional Brownian motion process $B_t = (B_t^1, B_t^2, \ldots, B_t^{n+m})$ defined on a filtered probability space $(\Omega, \mathcal{F}, P; \mathcal{F}_t)$. The volatilities σ, the instantaneous mean returns α of the risky assets, and the interest rate r of the riskless asset are affected by the economic factors $(X_t^1, \ldots, X_t^n)$ defined as the solution of the stochastic differential equation

$$dX_t = \beta(X_t)dt + \lambda(X_t)dB_t, \quad X(0) = x \in R^n.$$

Let us set the total wealth W_T of an investor to be $W_T = \sum_i N_T^i S_T^i$ with N_T^i, number of the share invested to ith security S_T^i at time T, and W_0 the initial wealth. Expected power utility maximization maximizing $\frac{1}{\gamma} E[W_T^\gamma] = \frac{1}{\gamma} E[e^{\gamma \log W_T}]$, $\gamma < 1, \neq 0$ (Merton 1990) is equivalent to

$$\sup \frac{1}{\gamma} \log E[e^{\gamma \log W_T}], \tag{8}$$

and it has been studied in terms of "risk-sensitive asset management." When introducing portfolio proportion h_t^i invested to ith security defined by $h^i(t) = \frac{N^i(t)S^i(t)}{W(t)}$ for each $i = 0, \ldots, m$ and setting $h(t)^* = (h^1(t), h^2(t), \ldots, h^m(t))$, the total wealth W_t turns out to satisfy

$$\frac{dW(t)}{W(t)} = \{r(X_t) + h(t)^*\hat{\alpha}(X_t)\}dt$$
$$+ h(t)^*\sigma(X_t)dB_t,$$

under the self-financing condition, where $\hat{\alpha}(x) = \alpha(x) - r(x)\mathbf{1}$, $\mathbf{1} = (1, 1, \ldots, 1)^*$. In considering the maximization problem, the portfolio proportion h_t is considered an investment strategy to be controlled and assumed to be $\mathcal{G}_t^{S,X} := \sigma(S(u), X(u), u \leq t)$ progressively measurable in the case of full information. The problem is often considered under partial information where h_t is assumed to be $\mathcal{G}_t^S := \sigma(S(u), u \leq t)$ measurable. Here we first discuss the case of full information, and the set of admissible strategies $\mathcal{A}(T)$ (or $\mathcal{A}$) is determined as the totality of $\mathcal{G}_t^{S,X}$ progressively measurable investment strategies satisfying some suitably defined integrability conditions.

Considering (8) for $\gamma < 0$ amounts to studying the minimization problem

$$\hat{v}(0, x) = \inf_{h. \in \mathcal{A}(T)} \log E[e^{\gamma \log W_T(h)}]. \tag{9}$$

Then introducing a probability measure p^h defined by

$$P^h(A) = E[e^{\gamma \int_0^T h_s^* \sigma(X_s) dW_s - \frac{\gamma^2}{2} \int_0^T h_s^* \sigma \sigma^*(X_s) h_s ds} : A],$$

$A \in \mathcal{F}_T$, the value function is expressed as

$$\hat{v}(0, x) = \gamma \log W_0 + \inf_{h. \in \mathcal{A}(T)}$$

$$\log E^h [e^{-\gamma \int_0^T \eta(X_s, h_s) ds}]$$

with the initial wealth W_0, where

$$\eta(x, h) = -h^* \hat{\alpha}(x) + \frac{1-\gamma}{2} h^* \sigma \sigma^*(x) h - r(x)$$

and $\hat{\alpha}(x) = \alpha(x) - r(x)\mathbf{1}$. By using the Brownian motion $B_t^h := B_t - \gamma \int_0^t \sigma^*(X_s) h_s ds$ under the new probability measure P^h, the dynamics of the economic factor X_t is written as

$$dX_t = \{\beta(X_t) + \gamma \lambda \sigma^*(X_t) h_t\} dt + \lambda(X_t) dB_t^h. \tag{10}$$

Thus, we arrive at the risk-sensitive control problem with the value function $\hat{v}(0, x)$ and the controlled dynamics X_t governed by (10). Note that $\frac{1-\gamma}{2} > 0$ for $\gamma < 1$ and that the case where $\gamma < 0$ is called risk averse, which we mainly discuss here. Then the corresponding H-J-B equation is deduced as

$$\begin{cases} \frac{\partial v}{\partial t} + \frac{1}{2} \text{tr}[\lambda \lambda^* D^2 v] + \frac{1}{2}(Dv)^* \lambda \lambda^* Dv \\ + \inf_h \{[\beta + \gamma \lambda \sigma^* h]^* Dv - \gamma \eta(x, h)\} = 0, \\ v(T, x) = \gamma \log W_0, \end{cases} \tag{11}$$

which can be rewritten as

$$\begin{cases} \frac{\partial v}{\partial t} + \frac{1}{2} \text{tr}[\lambda \lambda^* D^2 v] + \beta_\gamma^* Dv \\ + \frac{1}{2}(Dv)^* \lambda N_\gamma^{-1} \lambda^* Dv - U_\gamma = 0, \\ v(t, x) = \gamma \log W_0. \end{cases} \tag{12}$$

Here $U_\gamma = -\frac{\gamma}{2(1-\gamma)} \hat{\alpha}^* (\sigma \sigma^*)^{-1} \hat{\alpha} + r(x)$, $\beta_\gamma = \beta + \frac{\gamma}{1-\gamma} \lambda \sigma^* (\sigma \sigma^*)^{-1} \hat{\alpha}$ and $N_\gamma^{-1} = I + \frac{\gamma}{1-\gamma} \sigma^* (\sigma \sigma^*)^{-1} \sigma$. Under suitable conditions H-J-B equation (12) has a solution with sufficient regularities (Bensoussan et al. 1998; Nagai 2003). Moreover, identification

$$v(0, x; T) \equiv v(0, x) = \hat{v}(0, x) \tag{13}$$

can be verified. Further, $\hat{h}(t, X_t) = \frac{1}{1-\gamma} (\sigma \sigma^*)^{-1} \{\hat{\alpha}(X_t) + \sigma \lambda^* Dv(t, X_t)\}$ is the optimal investment strategy for problem (9) (Nagai 2003).

A typical example is the case of linear Gaussian model such that $r(x) = r$, $\alpha(x) = Ax + a$, $\sigma(x) = \Sigma$, $\beta(x) = Bx + b$, $\lambda(x) = \Lambda$, where A, B, Σ, Λ are constant matrices; a, b are constant vectors; and r is a constant. Then, the solution to (12) has an explicit representation as $v(t, x) = \frac{1}{2} x^* P(t) x + q(t)^* x + k(t)$, where $P(t)$ is the negative semi-definite solution to the Riccati equation

$$\dot{P}(t) + P(t) \Lambda N^{-1} \Lambda^* P(t) + K_1^* P(t) + P(t) K_1 + \frac{\gamma}{1-\gamma} A^* (\Sigma \Sigma^*)^{-1} A = 0, \quad P(T) = 0 \tag{14}$$

and $q(t)$, $k(t)$ are, respectively, the solutions to

$$\dot{q}(t) + (K_1 + \Lambda N^{-1} \Lambda P(t))^* q(t) + P(t) b + \frac{\gamma}{1-\gamma} (A^* + P(t) \Lambda \Sigma^*) (\Sigma \Sigma^*)^{-1} \hat{a} = 0, \quad q(T) = 0 \tag{15}$$

and

$$\begin{aligned} &\dot{k}(t) + \frac{1}{2} \text{tr}[\Lambda \Lambda^* P(t)] + \frac{1}{2} q(t)^* \Lambda \Lambda^* q(t) \\ &+ \frac{\gamma}{2(1-\gamma)} (\hat{a} + \Sigma \Lambda^* q(t))^* (\Sigma \Sigma^*)^{-1} \\ &(\hat{a} + \Sigma \Lambda^* q(t)) = 0, \\ &k(T) = \gamma \log W_0, \end{aligned} \tag{16}$$

where $K_1 := B + \frac{\gamma}{1-\gamma} \Lambda \Sigma^* (\Sigma \Sigma^*)^{-1} A$, $\hat{a} = a - r\mathbf{1}$ and $N^{-1} := I + \frac{\gamma}{1-\gamma} \Sigma^* (\Sigma \Sigma^*)^{-1} \Sigma$. In this case the optimal strategy has a more explicit form: $\hat{h}_t = \frac{1}{1-\gamma} (\Sigma \Sigma^*)^{-1} [\hat{a} + AX_t] + \frac{1}{1-\gamma} (\Sigma \Sigma^*)^{-1} [\Sigma \Lambda^* q(t) + \Sigma \Lambda^* P(t) X_t]$ (cf. Davis and Lleo 2008; Kuroda and Nagai 2002).

The economic factor X_t may be more suitably considered to be unobservable and then the problem should be formulated as the risk-sensitive stochastic control problem under partial information. Indeed, one can formulate the problem by regarding the log prices $Y_t^i := \log S_t^i$, $i = 0, 1, 2, \ldots, m$ as the observable quantities and the economic factor X_t as the unobservable system process. As for linear Gaussian models and hidden Markov models, the problems are reduced to the ones of full information by obtaining the relevant controlled dynamics in a finite dimension through deducing the filtering equation by

the methods of change of measure (Nagai 1999; Nagai and Runggaldier 2008). Further, one can obtain the explicit form of the optimal strategy, which is $\mathcal{G}_t^S$ measurable, in the case of linear Gaussian model (Nagai 1999) as the parallel result to the above.

Linear Gaussian models for $0 < \gamma < 1$ are extensively studied in Fleming and Sheu (1999, 2002). In that case, one concerns the problems

$$\sup_h \log E[e^{\gamma \log W_T(h)}], \qquad (17)$$

or

$$\bar{\chi}(\gamma) = \sup_h \overline{\lim_{T \to \infty}} \frac{1}{T} \log E[e^{\gamma \log W_T(h)}]. \qquad (18)$$

If $0 < \gamma$ is small, there is a stationary solution of (14) and the verification theorem holds for the problem on infinite horizon (so does for the problem on a finite time horizon). Further, under some conditions there is a threshold $\bar{\gamma}$ such that $\bar{\chi}(\gamma) = \infty$ for $\bar{\gamma} < \gamma$. To know explicitly the size of $\bar{\gamma}$ is important, while it is limited to the case of 1 dimension to be able to realize.

Problems on Infinite Horizon

The value for the problem on infinite time horizon counterpart of (9) is defined as

$$\hat{\chi}(\gamma) = \inf_{h. \in \mathcal{A}} \chi(h; \gamma), \qquad (19)$$

$$\chi(h; \gamma) = \lim_{T \to \infty} \frac{1}{T} \log E[e^{\gamma \log W_T(h)}]$$

when suitably setting the set $\mathcal{A}$ of admissible strategies. The corresponding H-J-B equation of ergodic type for the problem is seen to be

$$\begin{aligned} \chi(\gamma) = &\tfrac{1}{2}\mathrm{tr}[\lambda\lambda^* D^2 w] + \beta_\gamma^* Dw \\ &+ \tfrac{1}{2}(Dw)^*\lambda N_\gamma^{-1}\lambda^* Dw - U_\gamma. \end{aligned} \qquad (20)$$

However, when setting as $\mathcal{A} = \{h.|_{[0,T]} \in \mathcal{A}(T), \quad \forall T\}$, identification of $\hat{\chi}(\gamma)$ with the solution $\chi(\gamma)$ to the H-J-B equation (20) cannot be seen in general. Indeed, even in the case of

linear Gaussian model, such identification does not always hold (Fleming and Sheu 1999; Kuroda and Nagai 2002; Nagai 2003) if $\gamma < 0$. Instead, introduce the asymptotic value

$$\tilde{\chi}(\gamma) = \lim_{T \to \infty} \frac{1}{T} \hat{v}(0, x; T).$$

Then we can see that $\chi(\gamma) = \tilde{\chi}(\gamma)$ under sufficiently general conditions (cf. Hata et al. 2010; Nagai 2012).

In the case of the linear Gaussian model, the solution to the H-J-B equation of ergodic type is given by $w(x) = \frac{1}{2}x^* \bar{P} x + \bar{q}^* x$ with the stationary solutions $\bar{P}$ of (14) and $\bar{q}$ of (15), and if

$$\overline{P}\lambda\Sigma^*(\Sigma\Sigma^*)^{-1}\Sigma\Lambda^*\overline{P} < A^*(\Sigma\Sigma^*)^{-1}A$$

holds, then one can see that $\chi(\gamma) = \hat{\chi}(\gamma)$ (Kuroda and Nagai 2002). Further, the optimal strategy is given by $\hat{h}_t = \hat{h}(X_t)$, with $\hat{h}(x) = \frac{1}{1-\gamma}(\Sigma\Sigma^*)^{-1}[\hat{a} + \Sigma\Lambda^*\bar{q} + (A + \Sigma\Lambda^*\overline{P})x]$ (Kuroda and Nagai 2002). Decomposition as $\hat{h}_t = \frac{1}{1-\gamma}\hat{h}_t^1 + \frac{1}{1-\gamma}\hat{h}_t^2 := \frac{1}{1-\gamma}(\Sigma\Sigma^*)^{-1}[\hat{a} + AX_t] + \frac{1}{1-\gamma}(\Sigma\Sigma^*)^{-1}[\Sigma\Lambda^*\bar{q} + \Sigma\Lambda^*\overline{P}X_t]$ is regarded as a generalization of Merton's Mutual Funds Theorem (Davis and Lleo 2008; Merton 1990). Here $\hat{h}_t^1$ is a log utility portfolio (Kelly portfolio) (Kelly 1956). See also Nagai and Peng (2002) concerning the partial information counterparts of the results in Kuroda and Nagai (2002).

In relation to the above problems on mathematical finance, a new kind of problem studying

$$I(\kappa) = \lim_{T \to \infty} \frac{1}{T} \inf_{h \in \mathcal{A}(T)} \log P(\log W_T(h) \le \kappa T) \qquad (21)$$

for a given constant κ, arises, and it is called "downside risk minimization." The problem is considered "large deviation control" and can be discussed as the dual to risk-sensitive asset management (19) in the risk-averse case $\gamma < 0$ (Hata et al. 2010; Nagai 2011, 2012). Indeed, we obtain

$$I(\kappa) = -\inf_{k \in (-\infty, \kappa]} \sup_{\gamma < 0} \{\gamma k - \hat{\chi}(\gamma)\}.$$

Further, an asymptotically optimal strategy is given as follows. For given κ, take $\gamma(\kappa)$ which attains the supremum in $\sup_{\gamma < 0}\{\gamma \kappa - \hat{\chi}(\gamma)\}$, then the optimal strategy $\hat{h}(t, X_t), 0 \leq t \leq T$ for problem (9) with $\gamma = \gamma(\kappa)$ forms the asymptotically optimal strategy for (21). Historically, the studies of "upside maximization" concerning

$$\bar{I}(\kappa) = \sup_{h \in \mathcal{A}} \overline{\lim_{T \to \infty}} \frac{1}{T} \log P(\log W_T(h) \geq \kappa T)$$

have been preceding (cf. Pham 2003), and the duality relationship between this and (18) was discussed. To develop further studies for the problem, there are difficulties to know the size of $\bar{\gamma}$ (Cf. Fleming and Sheu 1999, 2002).

Robot Grasp Control

Domenico Prattichizzo
University of Siena, Siena, Italy

Abstract

Robotic grasping is the process of establishing
a physical connection between the robot (or an
appendage of the robot called the gripper) and
an external object in such a way that the robot
can exert forces and torques on the object. Grasp
control requires the satisfaction of contact con-
straints, of which two types are considered. Form
constraints specify geometric configurations of
the gripper that bring it into contact with the
object to be grasped. This article is principally
concerned with force constraints and force clo-
sure that specify forces exerted on the object
that are sufficient to lift, move, or otherwise
manipulate it.

Keywords

Force constraints; Force closure; Grasp con-
straints; Grasp matrix; Hand Jacobian; Twists;
Wrenches

Introduction

Grasp control refers to the art of controlling the
motion of an object by constraining its dynamics
through contacts with a hand. The process of con-
trolling the grasp is not limited to robotic hands
only but also applies to human hands (Johansson
and Edin 1991) and to all other mechanisms using
contact constraints to control the motion of the
manipulated object (Brost and Goldberg 1996).

A crucial role in the control of grasping is
played by contact constraints. All the interactions
between the robotic hand and the grasped object
occur at the contacts whose understanding is
paramount (Salisbury and Roth 1983). The uni-
lateral nature of contact interaction in grasping

makes the control problems much more challeng-
ing than cooperative manipulation where multiple
arms hold the object rigidly allowing bilateral
force transmission at each contact point (Chiac-
chio et al. 1991).

The importance of unilateral contact con-
straints in grasping led a large part of the
literature to focus on the closure properties
of the grasp (Bicchi 1995). Those properties
refer to the ability of a grasp to prevent
motions of the grasped object relying only
on unilateral frictionless constraints in case
of form closure (Reuleaux 1876) and on
contact constraints with friction in case of force
closure (Nguyen 1988). While form closure is
a purely geometric property of the grasp and
depends on where the unilateral contact points
are on the object, force closure depends on the
ability that the robotic hand has to resist and
apply forces to the object through the contacts
while satisfying the friction constraints. In other
terms force closure directly involves the control
of the robotic hand kinematics and not only the
geometry of the contacts (Bicchi 1995). This
entry focuses on force-closed grasps.

The optimal choice of the contact points on the
object surface is a critical issue known as grasp
planning. Among the many optimal criteria that
have been proposed in the literature to choose the
contact points, I want to recall the one proposed
in Ferrari and Canny (1992) where the grasp-
ing configuration is evaluated according to the
magnitude of the largest worst-case disturbance
wrench that can be resisted by the grasp.

Many approaches have been studied in the
literature on grasp planning in the presence of
uncertainties. The uncertainty can be either due to
the shape of the object which is partially known
or partially sensed as in Goldfeder et al. (2009)
or due to the errors in positioning the fingers on
the object during the grasping (Roa and Suarez
2009). In what follows all the parameters of the
grasp including those related to the hand, the
object, and the contact points are assumed to be
known with no uncertainties.

The main objective of grasp control is that of
tracking a desired trajectory with the grasped
object by applying a set of contact forces

satisfying the friction constraints (Bicchi and Kumar 2000). Complex in-hand object motions can be obtained by rolling and sliding the contact points on the object surface as proposed in Montana (1988) or by using finger gaiting to get large-scale motions (Han and Trinkle 1998). This entry deals with non-rolling and non-sliding contact points and summarizes the fundamental theory of computed-torque control for object trajectory and internal force control proposed in Li et al. (1989). For a comprehensive review of the theory of grasping and its control, the reader is referred to Murray et al. (1994), Shimoga (1996), Okamura et al. (2000), Bicchi and Kumar (2000), and Prattichizzo and Trinkle (2008).

Contact and Grasp Model

Notations and definitions on grasping are taken from Prattichizzo and Trinkle (2008). Refer to Fig. 1 and let $\{N\}$ represent the inertial frame fixed to the palm of the robotic hand. Let $u = [p^T, \phi^T]^T \in \mathbb{R}^6$ denote the vector describing the position and orientation of frame $\{B\}$, fixed to the object, relative to $\{N\}$. Vector ϕ expresses the

Euler angles, the pitch-roll-yaw variables, or the exponential coordinates parameterizing $SO(3)$. Denote by $\nu = [v^T \; \omega^T]^T \in \mathbb{R}^6$ the twist of the object. It is worth to note that ν is not equal to $\dot{u}$, but satisfies $\nu = U(u)\dot{u}$ where matrix $U \in \mathbb{R}^{6\times6}$ is such that UU^T is the identity matrix, and the dot over the variable implies differentiation with respect to time (Murray et al. 1994). The joint variables of the robotic hand are defined by $q = [q_1 \; \ldots \; q_{n_q}]^T \in \mathbb{R}^{n_q}$. Let n_c be the number of contact points. The position of contact point i in $\{N\}$ is defined by the vector $c_i \in \mathbb{R}^3$, in the contact point frame $\{C\}_i$ whose axes are $\{\hat{n}_i, \; \hat{t}_i, \; \hat{o}_i\}$ where the unit vector $\hat{n}_i$ is normal to the tangent plane at the contact, and directed toward the object while the other two unit vectors are orthogonal and lie in the tangent plane.

Two matrices are of utmost importance in grasp analysis: the *grasp matrix G* and the *hand Jacobian J*. These two matrices are computed using the complete grasp matrix, the complete Jacobian, and the contact selection matrix that are defined as follows: the transpose of the *complete grasp matrix* $\tilde{G}^T \in \mathbb{R}^{6n_c \times 6}$ maps the object twist to the n_c twist vectors of the contact frames $\{C\}_i$ as thought on the object $v_{c,\text{obj}} = \tilde{G}^T \nu$, while

Robot Grasp Control,
Fig. 1 A two-fingered hand grasping an object
the *complete hand Jacobian Matrix* $\tilde{J} \in \mathbb{R}^{6n_c \times n_q}$ maps the joint velocities to the twists of the contact frames as thought on the hand $v_{c,\mathrm{hnd}} = \tilde{J}\dot{q}$.

When a contact occurs between the hand and the object, assuming no sliding, some components of the relative contact twist between the object and the hand are set to zero according to the used contact model. In this entry the *hard-finger* (HF) and the *soft-finger* (SF) contact models are considered (Mason and Salisbury 1985). Those components are selected by the *contact selection matrix* which selects m components of the relative contact twists for all the contacts and sets them to zero: $H(v_{c,\mathrm{hnd}} - v_{c,\mathrm{obj}}) = 0$. For more details on how to compute the contact selection matrix, the reader is referred to Prattichizzo and Trinkle (2008). Then the following contact constraint equation is obtained:

$$\begin{bmatrix} J & -G^T \end{bmatrix} \begin{bmatrix} \dot{q} \\ v \end{bmatrix} = 0 \qquad (1)$$

where the transpose of the grasp matrix and the hand Jacobian are finally defined by multiplying the contact selection matrix and the transpose of the complete grasp matrix and the complete hand Jacobian as

$$G^T = H\tilde{G}^T \in \mathbb{R}^{m \times 6}$$
$$J = H\tilde{J} \quad \in \mathbb{R}^{m \times n_q}$$

In the force domain, the wrenches that the hand applies to the object at the contact points are collected in the vector λ. Correspondingly, on the hand, a force vector $-\lambda$, opposite to the preceding one, is applied by the object through the contact points. At each contact point, the contact wrenches have components only along the directions constrained by the contact model. Furthermore, contact force components must satisfy the friction constraints (see section "Force Closure and Grasp Control"). More specifically, the m-dimensional vector $\lambda = [\lambda_1^T \ \ldots \ \lambda_{n_c}^T]^T$ contains the contact wrench components applied to the object through the n_c contacts, where the wrench at contact i is defined, for the different contact models here considered, as $\lambda_i = [f_{in} \ f_{it} \ f_{io}]^T$ for the HF contact model and

$\lambda_i = [f_{in} \ f_{it} \ f_{io} \ m_{in}]^T$ for the SF contact model. The subscripts indicate one normal (n) and two tangential (t, o) components of contact force f_i and moment m_i at contact i.

In terms of forces, the grasp matrix maps the transmitted contact wrenches λ to the set of wrenches that the hand can apply to the object $G\lambda$, and the transpose of hand Jacobian maps the contact forces $-\lambda$ to the corresponding vector of joint loads $-J^T\lambda$.

Grouping all the noncontact wrenches applied to the object in $g \in \mathbb{R}^6$ and all the noncontact contributions to the joint loads of the robotic hand in $\tau \in \mathbb{R}^{n_q}$, the rigid-body dynamic equations of the whole system, consisting of the hand and of the grasped object, are

$$M_{\mathrm{obj}}(u)\dot{v} + N_{\mathrm{obj}}(u, v) = G\lambda + g$$
$$M_{\mathrm{hnd}}(q)\ddot{q} + N_{\mathrm{hnd}}(q, \dot{q}) = -J^T\lambda + \tau$$

where $M_{\mathrm{obj}}(\cdot)$ and $M_{\mathrm{hnd}}(\cdot)$ are symmetric, positive definite inertia matrices and $N_{\mathrm{obj}}(\cdot, \cdot)$ and $N_{\mathrm{hnd}}(\cdot, \cdot)$ are the velocity-product terms for the object and the hand, respectively. For the sake of simplicity, the gravity terms are disregarded.

The dynamics of the hand and object are not independent but depend on the kinematic constraints imposed by the contact model (1)

$$\begin{bmatrix} -G \\ J^T \end{bmatrix} \lambda = \begin{bmatrix} \overline{g} \\ \overline{\tau} \end{bmatrix} \qquad (2)$$

$$\text{subject to} \quad J\dot{q} = G^T v$$

where

$$\overline{g} = g - M_{\mathrm{obj}}(u)\dot{v} - N_{\mathrm{obj}}(u, v).$$
$$\overline{\tau} = \tau - M_{\mathrm{hnd}}(q)\ddot{q} - N_{\mathrm{hnd}}(q, \dot{q})$$

It is worth underlying that dynamics can be disregarded for slow motions of the hand and of the object, while it becomes very relevant in applications with high-speed grasping and manipulation as discussed in Namiki et al. (2003).

Controllable Wrenches and Twists

From the first equation in (2) to impose any motion to the object by contact forces, the grasp matrix G must be full row rank, i.e., $\text{rank}(G) = 6$, which is equivalent to have a trivial null space of G^T, i.e., $\mathcal{N}(G^T) = 0$. This is an important property of the grasp which has been referred to as *non-indeterminate* in Prattichizzo and Trinkle (2008) to reflect the idea that the contacts on the object are placed in a way that there are no twists of the object that are not controllable by contact wrenches.

However, this condition depends only on the contacts on the object and does not consider the role of the hand kinematics which comes from the second equation in (2) and from the contact constraint. Under the simplifying assumption that $\mathcal{N}(J^T) = 0$, referred to as *non-defective* grasp in Prattichizzo and Trinkle (2008), it is simple to verify that, for any given contact wrench λ, a control torque τ exists which is able to apply the given contact wrench. The mechanical interpretation of this assumption is that when $\mathcal{N}(J^T) = 0$, there are no contact forces resisted by the robotic hand constraints, i.e., with zero joint load. The simplifying assumption of non-defective grasps ensures that $\mathcal{N}(J^T) \cap \mathcal{N}(G) = 0$ which is a necessary condition to determine the contact force λ from the rigid-body equation (2) as shown in Prattichizzo and Trinkle (2008).

If a grasp is non-defective, it means that each finger of the robotic hand involved in the contact with the object must have a number of joints sufficient to control all the components of the contact wrench. For example, in the case of two HF contact points occurring at the fingertips of a two-fingered robotic hand, each finger must have at least three joints and must be in a non-singular configuration.

This entry does not consider whole-hand or power grasps which, differently from the fingertip grasps, exploit the whole surface of the fingers, including the palm, to constraint the object. The analysis of controllable wrenches and twists for whole-arm grasps, taking into account the hand and object dynamics, can be found in Prattichizzo and Bicchi (1997).

Force Closure and Grasp Control

The dynamic formulation of the grasp with the contact kinematic constraints given in (2) holds only if the contact forces satisfy the friction law imposing constraints on the components of the contact force and moment. Limiting the analysis to HF contact models, Coulomb friction law requires that the components of contact force λ_i at the i-th contact lie inside the friction cone $\mathcal{F}_i$

$$\mathcal{F}_i = \{(f_{in}, f_{it}, f_{io}) \mid \sqrt{f_{it}^2 + f_{io}^2} \le \mu_i f_{in}\} \tag{3}$$

where μ_i represents the friction coefficient at the i-th contact. Extending to all contact points, λ is constrained to lie in $\mathcal{F}$ where $\mathcal{F}$ is the generalized friction cone defined as: $\mathcal{F} = \mathcal{F}_1 \times \cdots \times \mathcal{F}_{n_c} = \{\lambda \in \mathbb{R}^m \mid \lambda_i \in \mathcal{F}_i; \ i = 1, \dots, n_c\}$.

While grasping an object, the applied contact forces must be consistent with the friction constraints. This is not straightforward for the grasp control and requires to exploit the beneficial characteristics of the internal forces. From the object dynamics in (2), for a given $\overline{g}$, one gets

$$\lambda = -G^+ \overline{g} + N(G)\gamma \tag{4}$$

where G^+ denotes the generalized inverse of the grasp matrix and $N(G)$ denotes a matrix whose columns form a basis for $\mathcal{N}(G)$, and γ is a vector parameterizing the solution set. The contact force λ consists of a particular solution balancing the $\overline{g}$ term and of a homogeneous solution belonging to the null space of the grasp matrix.

In general, the particular solution $-G^+ \overline{g}$ does not satisfy the friction constraint (3) at all the contact points and needs the homogeneous solution $\lambda_h = N(G)\gamma$ to keep the contact forces within the friction cones. Contact forces λ_h in $\mathcal{N}(G)$ are referred to as *internal forces* since they do not contribute to the object dynamics, i.e., $G\lambda_h = 0$. Instead, these forces affect the tightness of the grasp and play a crucial role in maintaining grasps that rely on friction. The existence of a nontrivial null space of the grasp matrix is a

R

desirable property and has been referred to as *graspability* (Prattichizzo and Trinkle 2008).

Another relevant and desirable property of the grasp is the *frictional force closure* which means that for any noncontact wrench $\overline{g}$, an internal force λ_h exists such that the contact force λ in (4) belongs to the generalized friction cone $\mathcal{F}$. In Murray et al. (1994) the authors state that a grasp has frictional form closure if and only if the grasp matrix is full row rank (non-indeterminate grasp) and there exists λ_h such that $G\lambda_h = 0$ and λ_h belong to the interior of the generalized friction cone $\mathcal{F}$.

Grasp control is about using contact forces, which must satisfy the friction constraints, so as to let the object to track a given trajectory. This is also referred to as dexterous manipulation (Bicchi and Kumar 2000). In Li et al. (1989), a computed-torque controller is proposed to track both the desired trajectory of the grasped object u_{des} and the desired internal force $\lambda_{h,\text{des}}$. Under the additional simplifying assumption that the robotic hand Jacobian is invertible, i.e., there are no redundant motions of the fingers, the computed-torque control law

$$
\begin{aligned}
\tau = & N_{\text{hnd}}(q,\dot{q}) + J^T G^+ N_{\text{obj}}(u,v) \\
& - M_{\text{hnd}} J(q) J^{-1} \dot{J} \dot{q} + M_{\text{ho}} \dot{U} \dot{u} \\
& + M_{\text{ho}} U(\ddot{u}_{\text{des}} - K_v \dot{e}_u - K_u e_u) \\
& + J^T(\lambda_{h,\text{des}} - K_s \int e_{\lambda_h}),
\end{aligned}
$$

with $M_{\text{ho}} = M_{\text{hnd}} J(q) J^{-1} G^T + J^T G^+ M_{\text{obj}} J$ guarantees that both the trajectory and the internal force errors

$$
e_u = u - u_{\text{des}}
$$

$$
e_{\lambda_h} = \lambda_h - \lambda_{h,\text{des}}
$$

with respect to the desired object trajectory u_{des} and internal force $\lambda_{h,\text{des}}$ converge to zero according to a second- and first-order dynamics, respectively.

$$
\ddot{e}_u + K_v \dot{e}_u + K_u e_u = 0
$$
$$
e_{\lambda_h} + K_s \int e_{\lambda_h} = 0
$$

where K_v, K_u, and K_s are positive definite matrices.

The computed-torque controller proposed in Li et al. (1989) guarantees only that the desired object trajectory and the desired internal forces are asymptotically tracked, but it does not ensure the non-violation of friction constraints by the contact forces. To guarantee that the contact force vectors remain in the friction cone during the manipulation, a force distribution problem must be solved at each time instant. The force closure assumption ensures that a solution exists that satisfies the friction constraints during the manipulation. This solution, which becomes the reference for the internal force control, can be found with an efficient algorithm, based on the minimization of a convex function that checks the force closure property at each time instant (Bicchi 1995).

Summary and Future Directions

The basic foundation of grasp control has been reviewed with a particular attention to modeling of contact constraints, force closure, and control of object motion and internal forces. This entry did not explicitly address grasp stability that is often equated to grasp closure, because all external forces can be balanced by the hand. A more formal analysis of grasp stability in terms of deflection from an equilibrium point has been proposed for hands with general kinematics in Jen et al. (1996).

The computed-torque control is a classical approach to the grasp control. For a deeper study of other approaches to grasp control based on passivity theory, the reader is referred to Wimboeck et al. (2011).

Recent developments in underactuated robotic hands Birglen et al. (2008) have led to a renewed interest in grasp control. Designing hand with a lower number of actuators has a lot of advantages in terms of robustness and reliability but dramatically reduces the dexterous manipulation abilities which can be recovered only by designing new control algorithms (Prattichizzo et al. 2013).

Recommended Reading

Grasp synthesis and dexterous manipulation are important research topics. Grasp synthesis is the problem of choosing the posture of the hand and contact point locations to optimize a grasp quality metric. One of the first studies of grasp synthesis for multi-fingered hands was undertaken in Jameson (1985) where the author proposed a Levenberg-Marquardt algorithm to search the surface of an object for the locations of three points that would achieve force closure. Since this work, many other metrics and approaches to searching for high-quality grasps have been implemented as discussed in Nguyen (1988), Pollard (1997), Park and Starr (1992), Chen and Burdick (1993), and references therein.

Dexterous manipulation is the capability of manipulating an object so as to arbitrarily steer its configuration in space. Research on dexterous manipulation first appeared in Hanafusa and Asada (1979) where the authors developed a plan to turn a nut onto a bolt. Since then a progression of increasingly complex manipulation tasks have been studied to varying degrees of detail. For the planar case the reader is referred to Mason (1982), Brost (1991), Peshkin and Sanderson (1988), Lynch (1996), and references therein. Several approaches have been proposed to planning and execute dexterous manipulation tasks in three dimensions continues in Cherif and Gupta (1999), Han et al. (2000), and Higashimori et al. (2007). Dexterous manipulation can be evaluated with manipulability ellipsoids of velocity and force as proposed in Chiacchio et al. (1991) for multiple-fingered systems and more recently in Prattichizzo et al. (2012) for underactuated robotic hands.

Computer Science, The University of Texas at
Dallas, Richardson, TX, USA

Abstract

The motion control problem for robots, both for
manipulator arms and for wheeled mobile robots,
is to determine a time sequence of control inputs
to achieve a desired motion, or output, response.
The control inputs are usually motor currents
but can be translated into torques or velocities
for the purpose of control design. The desired
motion is typically given by a reference trajec-
tory, consisting of positions and velocities that
are generated from motion planning and trajec-
tory generation algorithms designed to calculate
collision-free paths, taking into account various
kinematic and dynamic constraints on the robot.
In this chapter we give an overview of some
common control methods for motion control of
robots, concentrating on the control of manipula-
tor arms.

Keywords

Adaptive control; Feedback linearization; Inverse
kinematics; Motion planning; Passivity-based
control; PID control; Robust control

Introduction

We consider the motion control problem for an *n*-degree-of-freedom robot manipulator, such as shown schematically in Fig. 1. The variables $\theta_1, \ldots, \theta_n$ are the *joint variables*, which define the *configuration* of the robot at each instant of time.

A robot manipulator is fundamentally a positioning device *designed to move material, parts, tools, or specialized devices through variable programmed motions for the performance of a variety of tasks (Robot Institute of America, 1980)*. Thus, manipulator tasks, such as materials transfer, welding, and painting, and even tasks involving the control of interaction forces, such as assembly or grinding, are performed through the coordination and control of the motion of the joints of the robot.

A typical robot control architecture is shown in Fig. 2, which is designed to translate *sensing* into *action*, through motion planning, trajectory generation, and feedback control. In this entry we concentrate on the function of the controller.

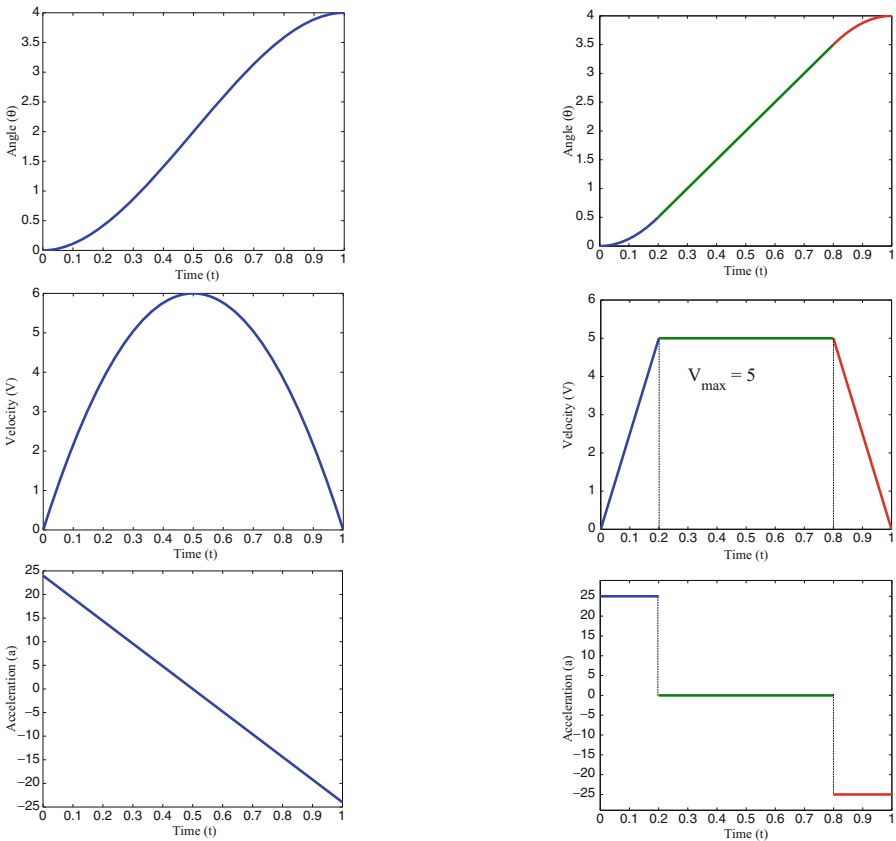
Motion Planning

The desired joint motions are specified as reference trajectories (positions and velocities) generated from motion planning algorithms that must determine collision-free paths taking into account various kinematic and dynamic constraints on the robot (Lavelle 2006). A detailed discussion of motion planning is outside the scope of this entry. The motion planning problem begins by decomposing a given task into a discrete set of end-effector motions. A continuous path for the end-effector in the *task space* is then computed, taking into account issues of joint limits and collisions with objects in the workspace, including self-collisions.

Finding optimal paths in configuration space is computationally complex, and methods have been developed to determine feasible, suboptimal paths using various methods such as artificial potential functions, grid search, and roadmaps (Lavelle 2006).

Once a feasible path in task space is determined, a *trajectory*, which is a time-parameterized function in task space or configuration space, is computed. To compute configuration space or joint space trajectories from task space trajectories, the *inverse kinematics* of the manipulator is used.

Trajectory Generation

To simplify computation, joint-level trajectories are typically generated by calculating the inverse kinematics only at discrete points along the task space trajectory and then interpolating between these points. Two of the most common interpolation schemes utilize either *polynomials* in time or *trapezoidal velocity* profiles.
For example, a *cubic polynomial* reference trajectory, $\theta^r(t)$, may be specified as


$$\theta^r(t) = a_0 + a_1 t + a_2 t^2 + a_3 t^3$$
Robot Motion Control,
Fig. 1 Six-link robot
manipulator

Robot Motion Control, Fig. 2 Control architecture for robot control

Robot Motion Control, Fig. 3 A cubic polynomial reference trajectory

Robot Motion Control, Fig. 4 Trapezoidal velocity profile

If the desired positions and velocities of the joint variable are specified at initial and final times, t_0 and t_f, respectively, it is a simple calculation to determine the four polynomial coefficients, $a_0, \ldots, a_3$. The reference velocity and acceleration are then given by

$$\dot{\theta}^r(t) = a_1 + 2a_2 t + 3a_3 t^2$$

$$\ddot{\theta}^r(t) = 2a_2 + 6a_3 t$$

A typical cubic polynomial trajectory is shown in Fig. 3.

A trapezoidal velocity profile is illustrated in Fig. 4.

In this case, the velocity of the joint angle increases linearly to a maximum value, $V_{\max}$,

which remains constant for a period of time and then decreases linearly.

Independent Joint Control

The simplest approach to control design for a multi-degree-of-freedom manipulator is to treat each link of the robot as a single-input/single-output (SISO) system and design the controllers independently for each link. *Proportional, integral, derivative (PID) control* is the most common method employed in this case. This approach works well for highly geared manipulators moving at relatively low speeds, since the large gear reduction and low speed tend to reduce the coupling effects among the various links. More advanced linear or nonlinear control methods can be used to achieve higher performance at the expense of added complexity of the control system.

The basic architecture of such a system, using a linear model to represent the dynamics of each joint of the robot, is shown in the frequency domain in Fig. 6.

The control design objective is to choose the compensator in such a way that the plant output θ *tracks* or follows a desired output, given by the reference signal, θ^r. The control signal, however, is not the only input acting on the system. *Disturbances*, which are really inputs that we do not control, also influence the behavior of the output. Therefore, the controller must be designed, in addition, so that the effects of the disturbance, D, on the plant output are reduced. If this is accomplished, the plant is said to *reject* the disturbances. The twin objectives of *tracking* and *disturbance rejection* are central to any control methodology.

The *plant* transfer function, $P(s)$, represents the dynamics of a single degree-of-freedom system, typically inertia and damping,

$$P(s) = \frac{1}{Js^2 + Bs} \quad (1)$$

$C(s)$ is a PID compensator

$$u(s) = \left(K_p + \frac{K_i}{s} + K_d s \right) (\theta^r(s) - \theta(s)) \quad (2)$$

where K_p, K_i, K_d are the proportional, integral, and derivative gains, respectively, and $\theta^r(s) - \theta(s)$ is the tracking error between the reference trajectory $\theta^r(s)$ and joint variable $\theta(s)$.

Set-Point Tracking

If the reference trajectory θ^r is a constant set point, then the closed-loop transfer function, $T(s)$, from θ^r to θ (with $D = 0$) is

$$T(s) = \frac{P(s)C(s)}{1 + P(s)C(s)}$$

$$= \frac{K_d s^2 + K_p s + K_i}{Js^3 + (B + K_d)s^2 + K_p s + K_i}$$

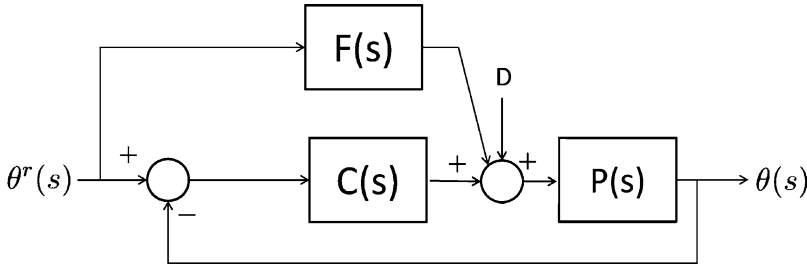
Applying the Routh-Hurwitz criterion, it follows that the closed-loop system is stable if the gains are positive and

$$K_i < \frac{(B + K_d)K_p}{J} \quad (3)$$

In addition, the presence of the integral control term, $\frac{K_i}{s}$, guarantees zero steady-state error to a constant disturbance term D.

Feedforward Control

In order to track nonconstant reference signals, such as a cubic polynomial trajectory or trapezoidal velocity trajectory, a feedforward term may be superimposed on the PID control signal as shown in Fig. 5. Under the condition that the plant $P(s)$ is *minimum phase*, the feedforward transfer function $F(s)$ can be taken as $1/P(s)$, the inverse of the plant. This guarantees asymptotic tracking of any time-varying reference trajectory provided the closed-loop transfer function is stable.

PID control is, by far, the most common type of control used in industry due to its simplicity. The main problem in implementing PID control is in the *tuning*, that is, in the choice of the


Robot Motion Control, Fig. 5 Feedforward control architecture
Robot Motion Control, Fig. 6 Single-axis control

proportional, derivative, and integral gains. As we see from the inequality (3), the magnitude of the integral gain K_i is limited by the stability constraint. Therefore, one common design rule of thumb is to first set $K_i = 0$ and design the proportional and derivative gains, K_p and K_d, to achieve the desired transient behavior (*rise time*, *settling time*, and so forth) and then to choose K_i within the limits imposed by (3) to remove the steady-state error.

Advanced Control Methods

Advanced control methods for robots generally aim to take into account issues such as dynamic coupling between joints; compliance in the joints or links; uncertainty in the inertia parameters, such as the masses and moments of inertia of the links; and robustness to sensor noise and other effects. A common model of the dynamics of n-link, rigid robots, i.e., without consideration of friction, elasticity in the joints or links, and other effects, is given by the so-called *Euler-Lagrange* equations

$$M(\theta)\ddot{\theta} + C(\theta, \dot{\theta})\dot{\theta} + g(\theta) = \tau \qquad (4)$$

where $\theta = (\theta_1, \theta_2, \ldots, \theta_n)^T$ is the vector of configuration (joint) variables as in Fig. 1. The n-dimensional vectors, $\dot{\theta}$ and $\ddot{\theta}$, are then the joint velocities and accelerations, respectively. The $n \times n$ matrix, $M(\theta)$, is called the inertia matrix. The vectors $C(\theta, \dot{\theta})\dot{\theta}$ and $g(\theta)$ are Coriolis and centrifugal forces and gravitational forces, respectively.

Equation (4) is a system of n coupled, nonlinear, second-order equations and is, in fact, a representation of Newton's Second Law of Motion, where the (generalized) forces acting on the joints of the robot $(\tau - C(\theta, \dot{\theta})\dot{\theta} - g(\theta))$ equate to the mass times acceleration, given by $M(\theta)\ddot{\theta}$.

In this case, the control problem becomes one of choosing the control input torque vector $\tau(t)$, as a function of time, so that the solution, $(\theta(t), \dot{\theta}(t))$, of Eq. (4) tracks a reference trajectory of joint positions and velocities, $(\theta^r(t), \dot{\theta}^r(t))$.

Feedback Linearization Control

An intuitive method of control for this system is the method of *feedback linearization*, which computes the input torque τ according to

$$\tau = M(\theta)a + C(\theta, \dot{\theta})\dot{\theta} + g(\theta) \qquad (5)$$

$$a = \ddot{\theta}^r + K_d(\dot{\theta}^r - \dot{\theta}) + K_p(\theta^r - \theta) \quad (6)$$

with K_d, K_p matrices of appropriate velocity and position error gains.

The control law given by Eqs. (5) and (6) is often referred to as the method of *inverse dynamics* although historically, the method of inverse dynamics control was implemented as a feedforward control

$$\tau = M(\theta^r)a + C(\theta^r, \dot{\theta}^r)\dot{\theta}^r + g(\theta^r) \quad (7)$$

$$a = \ddot{\theta}^r + K_d(\dot{\theta}^r - \dot{\theta}) + K_p(\theta^r - \theta) \quad (8)$$

using the reference position and velocity in place of the measured state. The primary reason for implementing the inverse dynamics in this fashion was the lack of sufficiently fast computation to enable computation of the terms in Eq. (5) in real time. The nonlinearities in Eq. (7) could be precomputed offline and stored to facilitate real-time implementation. With the advent of faster computers, the feedback linearization control is now feasible in real time.

Equations (5) and (6) form a so-called *inner-loop/outer-loop* architecture (Fig. 7). The significance of this architecture is that the nonlinear inner-loop control term (5) results in a linear system with input a and output θ. The design of the outer-loop control can then take advantage of control methods for linear systems. In fact, the control (6) in this case is simply a PD control with feedforward acceleration.

The result of the controller (5) and (6) is a closed-loop system in terms of the tracking error, $e(t) = \theta(t) - \theta^r(t)$, that satisfies the linear equation

$$\ddot{e} + K_d\dot{e} + K_p e = 0 \qquad (9)$$

and therefore, the tracking error converges exponentially to zero for any given reference trajectory.

Task Space Linearization

The inner-loop/outer-loop control architecture above can be modified to track trajectories directly in the task space. Moreover, one can achieve task space tracking by modifying only the outer-loop control a in Eq. (6) while leaving the inner-loop control (5) unchanged. Let $X \in R^6$ represent the end-effector position and orientation and let $X^r(t)$ be a reference trajectory in task space. Since X is a function of the joint variables θ, we have

$$\dot{X} = J(\theta)\dot{\theta} \qquad (10)$$

$$\ddot{X} = J(\theta)\ddot{\theta} + \dot{J}(\theta)\dot{\theta} \qquad (11)$$

where J is the manipulator *Jacobian*. If we now choose the outer-loop term a according to

$$a = J^{-1}\{a_X - \dot{J}\dot{\theta}\} \qquad (12)$$

with

$$a_X = \ddot{X}^r - K_0(X - X^r) - K_1(\dot{X} - \dot{X}^r) \quad (13)$$

we see that the result is a linear system in the task space tracking error $\widetilde{X}(t) = X(t) - X^r(t)$

$$\ddot{\widetilde{X}} + K_1\dot{\widetilde{X}} + K_0\widetilde{X} = 0 \qquad (14)$$

Robot Motion Control,
Fig. 7 Inner-loop/
outer-loop control
architecture

Therefore, a modification of the outer-loop control achieves a linear and decoupled system directly in the task space coordinates without the need to compute a joint space trajectory and without the need to modify the nonlinear inner-loop control.

It is important to note that the above result is valid in the case of six degree-of-freedom manipulators when the Jacobian J is square and invertible. The case when the Jacobian is not invertible, for example, at kinematic singularities, or when the number of joints is not equal to the dimension of the task space is outside the scope of this entry.

Robust and Adaptive Control

There are several theoretical and practical challenges to the method of feedback linearization control discussed in the previous section. For example, in order to compute Eq. (5), one must have exact knowledge of the parameters defining Eq. (4). In addition, effects of compliance, friction, and so on are not modeled by Eq. (4) and so the stability and performance of the system predicted by Eq. (9) may not be achieved in practice. This has stimulated a great deal of research into robust and adaptive control, control of elasticity, and other issues.

In distinguishing between robust control and adaptive control, we follow the commonly accepted notion that a robust controller is a fixed controller designed to satisfy performance specifications over a given range of uncertainties, whereas an adaptive controller incorporates some sort of online parameter estimation. This distinction is important. For example, in a repetitive motion task, the tracking errors produced by a fixed robust controller would tend to be repetitive as well, whereas tracking errors produced by an adaptive controller might be expected to decrease over time as the plant and/or control parameters are updated based on runtime information. At the same time, adaptive controllers that perform well in the face of parametric uncertainty may not perform well in the face of other types of uncertainty such as external disturbances or unmodeled dynamics.

Robust Feedback Linearization

If we denote by $\hat{M}(\theta)$, $\hat{C}(\theta, \dot{\theta})$, and $\hat{g}(\theta)$ expressions for the terms $M(\theta)$, $C(\theta, \dot{\theta})$, and $g(\theta)$ in the equations of motion (4) based on nominal or estimated values of the true parameters, we can define a control input

$$u = \hat{M}(\theta)(a + \delta a) + \hat{C}(\theta, \dot{\theta})\dot{\theta} + \hat{g}(\theta) \quad (15)$$

where a is as defined in Eq. (6) and δa represents an additional control intended to compensate for the parameter uncertainty. This leads to the state space model in terms of the tracking error e

$$\dot{e} = Ae + B\{\delta a + \eta\}$$

where η represents the *uncertainty* resulting from inexact cancellation of nonlinearities and

$$A = \begin{bmatrix} 0 & I \\ -K_0 & -K_1 \end{bmatrix}; \quad B = \begin{bmatrix} 0 \\ I \end{bmatrix}$$

Under the assumption that the uncertainty is bounded as $||\eta|| \leq \rho(e, t)$, the control term δa can be chosen as

$$\delta a = \begin{cases} -\rho(e, t)\dfrac{B^T Pe}{||B^T Pe||} & ; \text{ if } ||B^T Pe|| > \epsilon \\[2em] -\dfrac{\rho(e, t)}{\epsilon} B^T Pe & ; \text{ if } ||B^T Pe|| \leq \epsilon \end{cases}$$

The Lyapunov function

$$V = e^T Pe \quad (16)$$

where P is a symmetric, positive definite matrix satisfying a Lyapunov equation

$$A^T P + PA + Q = 0 \quad (17)$$

for a given symmetric positive definite matrix Q can be used to show uniform ultimate boundedness of all trajectories, where the size of the

ultimate boundedness set depends on ϵ. This is a practical notion of asymptotic stability in the sense that the tracking errors can be made small.

Passivity-Based Control

Passivity-based control is an alternative to feedback linearization control considered previously and relies on some fundamental structural properties of the Euler-Lagrange equations, primarily *linearity in the parameters* and *passivity*.

The *passivity property* (Ortega and Spong 1989) of robot dynamics follows from the fact that the matrix $N(q, \dot{q}) = \dot{M}(q) - 2C(q, \dot{q})$ is skew symmetric, that is, the components n_{jk} of N satisfy $n_{jk} = -n_{kj}$ (Spong et al. 2006). This property implies that the total energy E of the robot satisfies

$$\dot{E} = \dot{\theta}^T u \qquad (18)$$

and can be used to design provably correct robust and adaptive control laws.

Linearity in the Parameters

The robot equations of motion are defined in terms of certain parameters, such as link masses, moments of inertia, etc. The complexity of the dynamic equations makes the determination of these parameters a difficult task. Fortunately, the equations of motion are linear in these inertia parameters in the following sense: There exists an $n \times \ell$ matrix function $Y(q, \dot{q}, \ddot{q})$ and an ℓ-dimensional constant vector Φ such that the Euler-Lagrange equations can be written as

$$M(\theta)\ddot{\theta} + C(\theta, \dot{\theta})\dot{\theta} + g(\theta) = Y(\theta, \dot{\theta}, \ddot{\theta})\Phi \quad (19)$$

The function $Y(\theta, \dot{\theta}, \ddot{\theta})$ is called the *regressor* and $\Phi \in R^\ell$ is the *parameter vector*. The dimension of the parameter space, that is, the number of parameters needed to write the dynamics in this way, is not unique, and finding a minimal set of parameters that can parameterize the dynamic equations is difficult in general.

Passivity-Based Robust Control

The passivity and linearity-in-the-parameters properties of the robot dynamics can be exploited to design robust and adaptive controllers that do not attempt to cancel the system nonlinearities as in the inverse dynamics approach. A passivity-based robust controller may be defined as

$$u = \hat{M}(\theta)a + \hat{C}(\theta, \dot{\theta})v + \hat{g}(\theta) - Kr \quad (20)$$

where the quantities v, a, and r are given as

$$v = \dot{\theta}^r - \Lambda\tilde{\theta}$$
$$a = \dot{v} = \ddot{\theta}^r - \Lambda\dot{\tilde{\theta}}$$
$$r = \dot{\theta} - v = \dot{\tilde{\theta}} + \Lambda\tilde{\theta}$$

and K is a diagonal matrix of positive gains.

Using the linearity-in-the-parameters property, the closed-loop system can be written as

$$M(\theta)\dot{r} + C(\theta, \dot{\theta})r + Kr = Y(\theta, \dot{\theta}, a, v)$$
$$(\hat{\Phi} - \Phi) \qquad (21)$$

In the robust passivity-based approach, the term $\hat{\Phi}$ is chosen as

$$\hat{\Phi} = \Phi_0 + \delta\Phi$$

where Φ_0 is a fixed nominal parameter vector and $\delta\Phi$ is an additional control term. The additional term $\delta\Phi$ can be designed according to

$$\delta\Phi = \begin{cases} -\rho\dfrac{Y^T r}{||Y^T r||} & ; \text{ if } ||Y^T r|| > \epsilon \\[2ex] -\dfrac{\rho}{\epsilon}Y^T r & ; \text{ if } ||Y^T r|| \leq \epsilon \end{cases}$$

where ρ is a (constant) bound on the parameter uncertainty. Uniform ultimate boundedness of the tracking errors follows using the Lyapunov function

$$V = \frac{1}{2}r^T M(\theta)r + \tilde{\theta}^T \Lambda K \tilde{\theta}$$

where, as before, the size of the ultimate boundedness set depends on the parameter ϵ.

Passivity-Based Adaptive Control

In the adaptive version of this approach, we consider again the control law (20) and the resulting closed-loop system

$$M(\theta)\dot{r} + C(\theta, \dot{\theta})r + Kr = Y(\hat{\Phi} - \Phi)$$

In this case, the term $\hat{\Phi}$ is taken as the output of an estimator

$$\dot{\hat{\Phi}} = -\Gamma^{-1}Y^T(\theta, \dot{\theta}, a, v)r \qquad (22)$$

The Lyapunov function

$$V = \frac{1}{2}r^T M(\theta)r + \tilde{\theta}^T \Lambda K \tilde{\theta} + \frac{1}{2}\tilde{\Phi}^T \Gamma \tilde{\Phi}$$

can be used to show global convergence of the tracking errors to zero and boundedness of the parameter estimates.

One of the problems with the adaptive control approaches considered here is the so-called *parameter drift* problem. It can be shown that the estimated parameters converge to the true parameters provided the reference trajectory satisfies the condition of *persistency of excitation*

$$\alpha I \leq \int_{t_0}^{t_0+T} Y^T(\theta_r, \dot{\theta}_r, \ddot{\theta}_r)Y(\theta^r, \dot{\theta}^r, \ddot{\theta}^r)dt \leq \beta I$$

for all t_0, where α, β, and T are positive constants.

Summary and Future Directions

We have discussed the commonly applied methods of PID control, feedback linearization control, as well as robust and adaptive control for motion control of robot manipulators. There is a large and relatively mature body of literature on these methods, and in fact, the material here is now contained in standard textbooks in robotics, such as Siciliano et al. (2010) and Spong et al. (2006).

Future directions in robot motion control include the full integration of vision, force, and position feedback, cooperative control of multiple arms, and advances in machine learning and human-robot interaction. Direct control of robots through brain-machine interfaces is also an active area of research and will enable new areas of applications such as medical assistive robots.

Recommended Reading

Many of the fundamental theoretical problems in motion control of robot manipulators were solved during an intense period of research from about the mid-1980s until the early-1990s during which time researchers first began to exploit the structural properties of manipulator dynamics such as feedback linearizability, skew symmetry and passivity, multiple time-scale behavior, and other properties. For a more advanced treatment of some of these topics, the reader is referred to Spong et al. (1992) and Canudas de Wit et al. (1996).

A survey of robust control of robots up to about 1990 is found in Abdallah et al. (1991). The passivity-based robust control result here is due to Spong (1992). The first results in passivity-based adaptive control of manipulators were in Horowitz and Tomizuka (1986) and Slotine and Li (1987). The Lyapunov stability proof

of passivity-based adaptive control is due to Spong et al. (1990). A unifying treatment of adaptive manipulator control from a passivity perspective was presented in Ortega and Spong (1989).

Robot Teleoperation

Claudio Melchiorri
Dipartimento di Ingegneria dell'Energia Elettrica e dell'Informazione, Alma Mater Studiorum Università di Bologna, Bologna, Italy

Abstract

Robots may allow human beings to physically interact with remote objects and environments. This possibility is known as *robot teleoperation* and permits to operate in conditions or environments dangerous for human operators. Although teleoperation was among the first developments in robotics back in the 1950's, still nowadays there are important and difficult challenges for researchers and scientists, showing the intrinsic difficulties of this fascinating field of robotics.

Keywords

Bilateral control; Force reflection; Robot teleoperation; Time delay

Introduction

A robotic teleoperation system allows to reproduce the actions of a human operator and to interact physically with objects and environments placed at a distance. This possibility has always attracted the human being, and telemanipulation has been one of the first fields to be developed in robotics: the first modern applications of this type of technology are dated back to the 1940s and the early 1950s for handling radioactive material (Goertz and Thompson 1954), for underwater and space applications (Martin and Kuban 1985; Vertut and Coiffet 1986), and for human prostheses (Kobrinskii 1960). For an overview on applications, see Sheridan (1992), Hokayem and Spong (2006), Ferre et al. (2007) and the related references. Nevertheless, despite the research interest and the many existing devices, many

challenging problems have still to be fully solved both from the technical and control point of view.

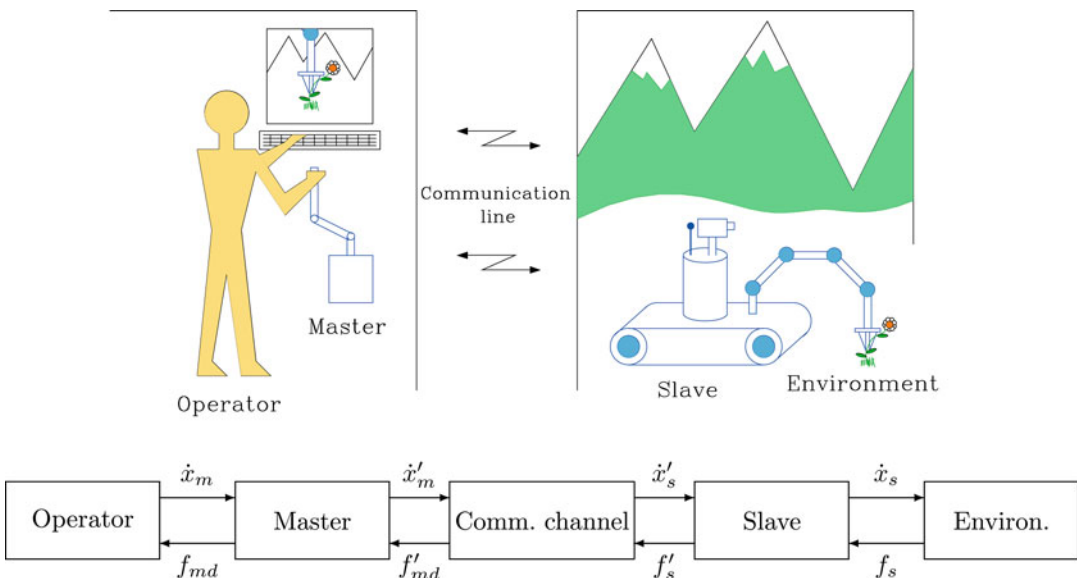
In these notes, an overview on robot teleoperation is presented. In particular, the following points are illustrated:

- General description of a telemanipulation system and of its key components: the "*master*," the "*slave*," and the "*communication channel*"
- Overview on applications and existing devices
- Some control techniques for telemanipulation systems: "traditional" force reflection, shared compliance control, Passivity-based control, predictive control, four-channel architecture

General Description of a Telemanipulation System

A telemanipulator is a complex mechatronic system in which the main elements are a *master* (or local) and a *slave* (or remote) device, interconnected by a *communication channel*. The overall system is interfaced on one side (the master) with a human operator and on the other (the slave) with the environment: see Fig. 1.

Both the master and slave devices have a local controller, with a hardware/software complexity that can be quite different depending on the system and task to be executed. Key features of this type of devices, usually not present in a typical robotic manipulation system, are:

1. A human operator is involved in the loop for the (high-level) control of the task execution.
2. It is necessary to provide to the operator, possibly in real time, data related to the task. This implies the presence of a suitable user interface and the selection of proper signals transmitted to the operator. These signals, e.g., related to forces applied to the environment, relevant positions of the slave, graphical video data, and tactile or acoustic information, have strong implications on the control properties and performances of the system.
3. A communication channel is present between the master and the slave. This channel may represent a source of problems when time-delays are present since, as well known from the control theory, delays in a feedback loop may generate instability. Problems of this type, firstly observed in a force feedback scheme in 1965 (Ferrel 1966), arise, for example, in underwater or space operations. Note that even time-delays of the order of the tenth of a second may create instability problems.


Robot Teleoperation, Fig. 1 A telemanipulation system and its block scheme representation. Subscripts m and s refer to variables at the master and slave site, respectively

In the block diagram of Fig. 1, some implicit choices have been made. The operator specifies a desired velocity ($\dot{x}_m$) to be applied to the environment through the master, the communication channel, and the slave and receives back a force signal (f_{md}). In the figure, the flow of the signals could be reversed as well, letting the operator specify a force to the environment and receiving back a velocity information. This is equivalent to reversing the roles of the master and slave devices. When this operation is possible, the teleoperation system is defined *bilaterally controlled* (Bejczy and Handlykken 1981).

One of the goals of the control system is to have, in steady state, the slave velocity equal to the master velocity, i.e., $\dot{x}_s = \dot{x}_m$, and similarly for the forces, $f_{md} = f_s$. When this is accomplished, the teleoperator is defined *transparent* (Lawrence 1993).

In this general framework, the main features of the components of a telemanipulator are the following.

The Master

The master, or local system, is the interface through which the operator specifies commands to the whole device. Typical features of the master are:

– Capability of assigning tasks to the slave and providing the operator with relevant information about the task development. In fact, an important feature of the master is its capability of providing the operator with the *telepresence*, i.e., the sensation of being in some manner involved with task execution. In this respect, several solutions have been adopted, varying from joysticks and/or consoles (Hirzinger et al. 1992) to exoskeletons (Bergamasco et al. 2007; Smith et al. 1992) and so on. In these devices, different types of signals may be reflected to the operator, from simple graphical data to full kinetostatic information.
– Capability of acquiring and processing data from both the operator and the slave. Typical elaborations are filtering, prediction, delay compensation, modeling of remote and local dynamics, and so on.

The Slave

The slave, or remote system, is the part of the teleoperator which directly interacts with the environment for task execution. Requirements similar to the master may be specified for the slave system:

– A robotic system for the interaction with the environment and the execution of the task planned by the operator. This part, usually provided with autonomous features, has to be in some way customized to operate in particular environments, e.g., submarine, outer space, and nuclear areas. Note that the kinematics and the dynamics of the remote manipulator may be different from those of the local one (when present), originating several problems when telepresence is needed for task execution (Colgate 1993).
– Signal acquisition and processing. Sensory capability is a main requirement for the slave device, which is often equipped with video cameras, force/tactile sensors, proximity sensors, and so on.
– Capability of data processing. Also the remote site must be able to elaborate the information needed for task execution. In fact, besides other considerations, the destabilizing effects caused by communication delays and/or restricted bandwidths of transmission must be compensated locally, providing the slave system with a certain degree of autonomy.

The Communication Line

The communication line represents the link between the master and slave sites. Different platforms may be used for this purpose, from radio connections by means of satellites to cables for underwater operations. The main drawback that can be introduced by this element is a delay, due both to a physical delay in the transmission line (e.g., in a long satellite communication) and to limited bandwidth of the hardware. This delay, that sometimes is not even constant, can cause noticeable instability problems if proper compensating actions are not taken.

An Overview on Applications

Use of telemanipulators, in the broader sense of the terminology, may be found in a number of different applications developed since the early 1950s. First examples of these devices have been designed and realized for operations in radioactive environments and for human limb prostheses. At the moment, this type of technology is applied in a number of different fields: space, underwater, medicine, hazardous environments, security, simulators, and so on.

Space Applications

Robotics is used in space for exploration, scientific experiments, and commercial activities. Main reasons of space telerobotics are the high costs and the hostile environment for human beings. For many years, the main example of teleoperation in space was applications in space shuttle activities where the operators had a direct control of the task executed by the manipulator. Nowadays, an important application of robot technology is for planetary missions, where autonomous telerobots are required and the operator has only a supervisory control of the task. Main directions of current research activity for space robotics are the development of arms for both intra-vehicular and extravehicular activities, free-flying platforms, and planetary rovers.

Among the most known examples of robot arms for space one can list the Canadian Remote Manipulator System (RMS), installed on the US space shuttles. The 6 degree-of-freedom (dof) arm, built by the Canadian firm SPAR, had a flexible, 15 m long structure and was capable of executing preprogrammed and/or teleoperated tasks. Five arms have been built, working on space shuttles from 1981 to 2011. Since 2001 the Canadarm 2 is used on the ISS (International Space Station). This 7 dof, 17.6 m long arm is used for assembly and maintenance purposes.

Concerning planetary exploration, a first successful space telerobotic program has been the Mars Viking Program, which performed scientific experiments on Mars in 1976. More recently, NASA has sent to Mars the rovers Sojourner in 1997 (working for about 3 months) and Spirit and Opportunity, which arrived in 2004. Opportunity is still working (January 2014), see http://marsrovers.jpl.nasa.gov/home/index.html. New missions on Mars with other, more complex, rovers are currently planned by NASA.

With the current technological possibilities, further substantial developments in this field are slowed down by the large amount of money and time required to guarantee a successful mission. However, relevant technical problems still exist due to reliability requirements, weight constraints, hostile environments and communication time-delays (ranging from 1 s in earth orbits to 4–40 min or more for planetary missions).

Underwater

After the first successful military applications of underwater telerobotics (in 1966 the US Navy's CURV – Cable-controlled Underwater Recovery Vehicle – was successfully employed to retrieve a nuclear bomb from the ocean), extensive use of ROVs (remote operated vehicles) has started in the 1980s for offshore operations for oil/gas industry. At the moment, underwater telerobotics is mainly used for business, military missions, and scientific expeditions. Telerobotic (autonomous) tasks are usually limited to small routine tasks rather than complete activities, for example, simple tool switching operations, repetitive bolt/nut screwing, and piloting to new locations. First examples of underwater teleoperation were mainly based on manned submersibles, either free swimming or connected to a surface ship, and with teleoperated arms on the outer structure. In more recent operations, human operators remotely control the submersibles by long fiber-optic cables for data communication, increasing the costs and complexity of the missions.

Probably, the most important users are in the business field, where it is more convenient to use teleoperated devices rather than human divers to perform inspections and repairs on deep sea equipment. The main users of telesubmersibles are the oil and communication (telephone) industries, where underwater pipes and cables require routine operations. The scientific community uses this technology for marine biological,

geological, and archeological missions, while the military have used telerobotics in many salvage operations, such as plane or watercraft recovery.

The conditions of the water environment, e.g., the high pressures, the poor visibility, and the communication difficulties, cause the major problems in this field. In order to solve the problems due to the high pressure, a very robust mechanical structure and (typically) hydraulic actuators are employed. On the other hand, vision problems are not so easily solved, being related to several factors of the environment. External lighting is necessary, and other technologies (e.g., sonar) are sometimes used. Computer graphic simulation may help the user during task execution in partially known environments. For references, see, e.g., Ridao et al. (2007).

Medical Telerobotics

Several teleoperated devices are found in the medical field. In fact, robotic manipulators are used to perform surgery, diagnose illnesses or injuries, help impaired people, and train specialized medical personnel.

Robotic systems of different complexities have been developed since the 1950s for aid to impaired people. Among the most common systems are automated wheelchairs, controlled by voice or by joysticks for hand, mouth, eye, or head movements.

At the moment, there is a relevant interest in applying teleoperated devices in microsurgery operations, e.g., eye surgery, where small precise movements are needed. The movements of the operator are scaled down by the mechanism so that very fine operations can be performed while maintaining a suitable telepresence effect. Another important class of surgical process consists of the so-called minimally invasive procedures. In this case, the surgeon operates through small insertions using thin medical instruments and small video cameras. The increased difficulties for the surgeon are partially compensated by computers, which are used to create virtual environments where the use of telepresence plays a fundamental role.

A very attractive application is the use of telemanipulators in remote surgery operations.

Telediagnosis may also broaden the range of a single doctor by allowing to exam a patient visually or viewing records on a computer interface. Finally, telepresence is becoming very important for the instruction of specialized doctors and to perform rehearsals before the actual operation.

Security

Applications in this area aim to employ telerobotic devices for the protection of persons and properties. Most systems used in this area are teleoperated devices since these tasks require decision capabilities and intelligence levels not currently possible for machines, although the use of autonomous systems is more and more frequent.

In the area of security, robots may be used for patrolling buildings and for protection purposes. These devices can either be autonomous or teleoperated. Military applications adopt principally teleoperation, mainly for locating enemies or dangerous equipment without direct risk for human personnel. Unmanned aeroplanes or teleoperated devices for the detection and destruction of mines or bombs are well-known examples of this technology. Teleoperation is also used for fire extinguishing, in order to spray water or chemical agents with remotely operated vehicles.

Telerobotics in Hazardous Environments

Robots may substitute human beings for operations in hazardous environments; as a matter of fact, nuclear industry was the first important user of modern teleoperating devices. Telerobotics is applied in several nuclear or chemical plants and also for military applications (e.g., for building military equipment and arms) in a variety of tasks. Besides direct handling of radioactive or chemical material, robots are used in waste cleanup/disposal and plant inspection. Ammunition disposal also makes use of telerobotic machines.

Telerobotics in Mining and Other Industries

Besides the typical use of robots in a number of industrial applications (assembly, welding, painting, and so on), other applications of robotic

R

systems in nonconventional production processes have been developed, for example, in mines, constructions, agriculture, warehousing, and many other activities.

Use of telemanipulators for mining applications, despite the relevant motivations such as high costs and risks of human work, finds difficulties and limitations caused by the particular environment and the relevant level of autonomy requested to operate in mines. As a matter of fact, the mining industry has only recently started to experiment teleoperated devices; see e.g., Duff et al. (2010). These machines are being developed to perform frame wall building, structure testing, hole drilling, wall blasting, mine digging, and so on.

In construction tasks, not considering that all construction/destruction machinery controlled by a human can be regarded as examples of teleoperators (e.g., cranes and front-end loaders), applications of real telerobotic systems are not so numerous because of the unstructured environments and the nonrepetitive tasks. Current work in this area concerns the development of machines for earth movement, construction of structures, building window washing, bridge inspection and maintenance, and power line repair.

The Control Problem

For the development of a reliable teleoperation system, providing force feedback to the user, the problems caused by the interaction of the robotic device with the environment and the possible time-delays caused by the communication channel have to be properly considered and solved.

In telemanipulation without either force feedback to the operator or a local compliance control, the remote manipulator is strictly controlled according to the master position signal. As a consequence, the system results in being stiff, and errors between the master and slave positions may cause excessive and undesired contact forces.

In bilateral telemanipulation, it has been proven that a profitable manner for increasing system performances (e.g., in terms of task completion time, total contact time, and cumulative contact force) is to reflect back to the operator information about the force applied to the environment. On the other hand, it results that the force reflection gain, that gives to the operator the feeling of the interaction, destabilizes the system, especially when time-delays are present.

Control schemes for robotic teleoperation devices can be classified according to the general structures reported in Fig. 2, showing the *direct teleoperation*, the *coordinated teleoperation*, and the *supervisory control* schemes. In the direct teleoperation scheme, possible only for negligible time delays, the operator has direct control of the slave robot and receives feedback in real time. In the coordinated teleoperation scheme, the operator still controls the remote robot, but low-level control loops in the slave system are present because time delays do not allow the operator to control directly the actuators. In the supervisory control scheme, the remote site has more autonomy and task execution is controlled locally, while the operator gives mainly high-level commands and acts as a supervisor. A local loop is present also at the master side, indicating the presence of (usually) a model (graphical, mathematical, etc.) of the slave site to improve performances in case of large time delays.

Some of the main control architectures for teleoperation devices presented in literature to deal with the problems of time-delay and force reflection are now briefly described and commented. The considered architectures are the *"traditional" force reflection*, the *shared compliance control*, the *passivity-based teleoperation*, the *predictive control*, and the *four-channel scheme*. However, many other control schemes have been presented in the literature; see, e.g., Arcara and Melchiorri (2002), Hirche et al. (2007), and therefore what is presented here is a brief, though significant, overview in order
Robot Teleoperation, Fig. 2 Possible structures of bilateral control schemes for robotic teleoperation

Robot Teleoperation, Fig. 3 The "traditional force reflection" transmission scheme
to focus on the major problems encountered in this field and on some of the approaches for their solutions.

Traditional Force Reflection Teleoperation

The simplest manner of transmitting the remote force to the operator is to reflect it directly, without any particular elaboration, as shown in Fig. 3. The resulting transmission equations are

$$\begin{cases} f_{md}(t) = f_s(t - T) \\ \dot{x}_{sd}(t) = \dot{x}_m(t - T) \end{cases} \tag{1}$$

where T is the time-delay introduced by the communication network and subscript d indicates the desired set point for the master (m) and slave (s) controllers.

This technique presents relevant instability problems due to time-delays. As a matter of fact, it is possible to verify that the communication channel does not present strictly passive properties, even for limited bandwidths of the input signals $\dot{x}_m$ and f_s. This result is valid also considering an attenuation between f_{md} and f_s, i.e., introducing a force reflection gain $G_{fr} < 1.0$ in (1) and computing therefore $f_{md}(t) = G_{fr} f_s(t - T)$. The attenuation reduces the telepresence sensation and degrades the performances, but still does not cause a passive (then stable) network. The nonpassive channel has the global effect of introducing in the overall system energy flows that, if not properly reduced by the local controllers, contribute to destabilize the telemanipulator.

The dynamics of the overall system may be described by the following two sets of equations: the first taking into account the master dynamics and the force transmitted by the communication channel and the second including the slave dynamics, the position signals of the channel, and the local position controller:

R

$$\begin{cases} M_m \dot{x}_m(t) = -f_{md}(t) - B_m \dot{x}_m(t) - K_h x_m(t) \\ f_{md}(t) = f_s(t - T) \end{cases} \qquad \begin{cases} M_s \dot{x}_s(t) = f_s(t) - B_s \dot{x}_s(t) \\ \dot{x}_{sd}(t) = S_p \dot{x}_m(t - T) \\ f_s(t) = K_p[x_{sd}(t) - x_s(t)] \end{cases}$$

In the above equations, M_i and B_i, $i = m, s$, are masses and damping factors at the master and slave sites, K_h represents the operator (simply modeled as a stiffness) and K_p the slave position controller. The gain S_p has been added, with respect to Eq. (1), in order to scale velocity variables between the two robotic systems.

It can be shown that this control scheme does not guarantee stability in the presence of time delays, although in practical applications stability may still be achieved for small time delays due to dissipation introduced by friction and the local controllers.

Shared Compliance Control

As previously mentioned, both the interactions of the robotic device with the environment and the effects of time-delays have to be considered in the definition of control strategies for telemanipulation systems. The *position-error based force reflection* scheme deals with both these effects (Kim et al. 1992). This scheme is based on the computation of the feedback signal f_{md} as a force proportional to the error between master and slave positions:

$$f_{md}(t) = G_{fr}[x_m(t) - x_s(t - T)]$$

This signal gives to the operator a sensation related to the difference between the postures of the robotic devices caused either by interactions or delays. Note that in this manner an elastic (proportional) element is introduced between the positions of the robots. This allows to obtain a stable behavior of the overall system comprehensive of local controllers, at least for limited values of G_{fr}.

An additional feature for dealing with problems due to time-delays is the so-called *shared compliance control* (SCC). A local, autonomous force feedback is realized at the slave site in order

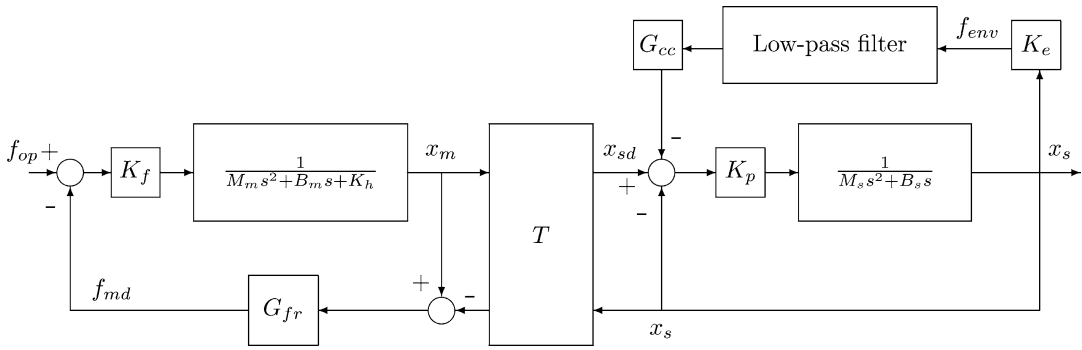
to program active compliance and damping of the robotic device. This control action is important when compliance has to be realized between the (stiff) mechanical device and its environment and during the collision or contact phases. The overall control system is therefore based on sharing autonomous and human-driven control actions. A block diagram of the whole system, including the master and slave dynamics ($1/(M_m s^2 + B_m s + K_h)$ and $1/(M_s s^2 + B_s s)$ respectively), the force reflection gain (G_{fr}), the shared compliance controller (G_{cc}), and an environment model (K_e), is shown in Fig. 4.

For a given time-delay, the force reflection gain G_{fr} can be increased with respect to the traditional force reflection scheme. In any case, when the time-delay increases, the gain has to be correspondingly decreased to guarantee stability, i.e., the value of G_{fr} depends directly on the amount of time-delay. In fact, also this control scheme in general does not present passivity features, although it can be shown that it may be stable (for a limited range of time delays) with a proper choice of the control parameters.

Passivity-Based Teleoperation

A control scheme inspired by the passivity theory (Van der Schaft 2000) is now described. Basic consideration is that the communication channel may represent, if proper actions are not taken, a non-passive element between the master and slave. With proper modifications, the transmission line presents passive properties, and therefore, the stability of the overall system may be achieved for any value of the time-delay T.

Lossless Transmission Line

Results of passivity and scattering theories can be used to show that in traditional force reflection teleoperation, Eq. (1), the instability of the overall system in presence of time-delays is caused by


Robot Teleoperation, Fig. 4 Position-error based force reflection with SCC at the remote site

the non passive properties of the communication channel (Niemeyer and Slotine 1991). On the other hand, it has been shown that the definition of a communication network based on a lossless transmission line provides the system with passivity features for any time-delay (Anderson and Spong 1989), facilitating therefore the stability of the overall system.

For the definition of a lossless transmission line, it is convenient to refer, instead of the velocity and force variables $\dot{x}$, f at each port (see Fig. 3), to the equivalent *wave* variables u and v that are related to the passivity formalism and whose definition derives from the theory of electric circuits. By using these variables, it is possible to describe the power balance in a circuit as the difference of two positive terms which consider the input and the output power. In fact, by introducing the input wave $u = [u_m^T, u_s^T]^T$ and the output wave $v = [v_m^T, v_s^T]^T$, the power balance in the teleoperator can be expressed as

$$P = \frac{1}{2}\left(u^T u - v^T v\right) = f^T \dot{x} = [f_m^T, f_s^T]\begin{bmatrix} \dot{x}_m \\ -\dot{x}_s \end{bmatrix}$$

By considering a proper scaling factor b, defined as the *characteristic impedance* of the transmission line, the previous equation defines the following transformations between power and wave variables:

$$u_m = \frac{1}{\sqrt{2b}}(f_m + b\,\dot{x}_m) \quad u_s = \frac{1}{\sqrt{2b}}(f_s - b\,\dot{x}_s)$$
$$v_m = \frac{1}{\sqrt{2b}}(f_m - b\,\dot{x}_m) \quad v_s = \frac{1}{\sqrt{2b}}(f_s + b\,\dot{x}_s)$$

The resulting network is described by

$$\begin{cases} f_{md}(t) = f_s(t - T) + b[\dot{x}_m(t) - \dot{x}_{sd}(t - T)] \\ \dot{x}_{sd}(t) = \dot{x}_m(t - T) + \frac{1}{b}[f_{md}(t - T) - f_s(t)] \end{cases}$$

In terms of wave variables, the passivity-based communication network is described as (see Fig. 5)

$$\begin{cases} f_{md}(t) = b\,\dot{x}_m(t) + \sqrt{2b}\,v_m(t) \\ \dot{x}_{sd}(t) = -\frac{1}{b}[f_s(t) - \sqrt{2b}\,v_s(t)] \end{cases}$$

In analogy with electric networks, impedance adaptation should be added to both extremities of the transmission line, as described e.g., in Niemeyer and Slotine (1991).

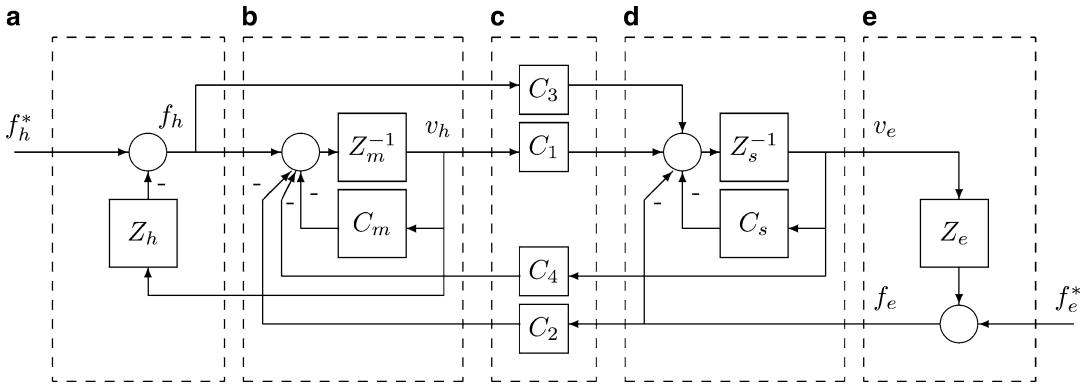
Predictive Control

In a well-known example of space telerobotics, the ROTEX project (Hirzinger et al. 1992), the problems introduced by force feedback and time-delays have been solved in a different manner. In fact, in this case the force information is not transmitted to the operator, and an extensive use of graphic simulation and *telesensor programming* is made to help control of the task execution.

In particular, the *predictive display* technique (Sheridan 1992) has been employed for generating and extrapolating beforehand visual indications, such as cursors or wire frame models of the manipulator and its environment. These information are generated by the control system and assist the operator in driving the task
Robot Teleoperation, Fig. 5 Transmission line based on passivity

execution more efficiently. In this case, a proper prediction algorithm has to be set on the basis of current initial conditions of the manipulator and, possibly, of current control variables.

In telerobotics, predictive displays have to be purposely designed in order to consider the prediction of motions of the manipulator. Usually, the task is graphically simulated in real time, without time-delay, exploiting a model of the remote environment and of the slave device. The operator can observe the task executed by the remote system on the screen, where a simulated copy (with $T = 0$ s) of the robotic device can be superimposed on the real operating device in the scene of the remote site. In this manner, the operator may program appropriate actions for the interaction with the environment.

This type of task planning helps when a noticeable time-delay occurs. In fact, when operators deal with relevant time-delays (e.g., larger than 1 s), usually they operate with a "move and wait" strategy, conservatively specifying only small displacements to the remote robot. By using predictive display, the time required to execute complex tasks is greatly reduced. On the other hand, the operator has only visual information about the remote environment and the task execution.


Four-Channel Scheme

A generalization of the scheme of Fig. 1, the so-called four-channel architecture (Hirche et al. 2007; Lawrence 1993), is shown in Fig. 6. In this scheme, both the velocity and force signal of

the master and slave are transmitted, and with a proper choice of the four blocks C_1, C_2, C_3, and C_4 many design goals can be achieved, in particular concerning the stability and the transparency of the overall system. In particular, if $C_3 = C_4 = 0$, the standard velocity-force transmission scheme is obtained, while ideal transparency is achieved if $C_1 = Z_{cs}$, $C_2 = C_3 = I$, $C_4 = -Z_{cm}$. In the figure, the blocks Z_m and Z_s represent the master and the slave dynamics (impedances), respectively, while C_m and C_s are the local master and slave controllers, f_h^* is an external force applied by the user, and f_e^* an exogenous force from the environment.

Summary and Future Directions

In these notes, an overview on telemanipulation has been presented with the aim of giving a general presentation of the impact of this area of robotics on both industry and research, of outlining typical problems encountered in dealing with remote manipulation systems, and of illustrating some approaches for their solution.

In this respect, it has to be pointed out that, besides the control schemes considered in these notes (purposely developed for telerobotic systems), many other schemes have been presented in the literature (see, e.g., Hokayem and Spong 2006, Ferre et al. 2007, and Arcara and Melchiorri 2002). More in general, however, a relevant literature exists, and important results have been presented from a methodological point of

Robot Teleoperation, Fig. 6 Block scheme of the four-channel architecture. (**a**) The human operator. (**b**) Master controller. (**c**) Communication line. (**d**) Slave controller. (**e**) Environment

view to face control problems of time-delay systems: see for example, Gu et al. (2003).

There are, however, other important aspects of telemanipulation which, for space constraints, can only be mentioned here, such as the "impedance shaping" (typical in applications in which there is a relevant dynamic/mechanical difference between the master and slave mechanisms) or criteria for defining (and measuring) performance of teleoperator systems, such as the "time to completion," criteria based on energy consumption, dexterity, and so on. Other interesting, and important, extensions are the possibility of controlling remote teams of robots cooperating for the execution of a common task (e.g., for aerial inspections, transport of heavy loads, etc.).

Future developments of robotic teleoperation systems will deal with the technological improvements of the user interface, giving to the operator more "realistic" feedback of the remote environment, the application of this type of technology to more complex situations, and the use of multi-robot systems controlled either by one or more cooperating users. Control will play in any case a fundamental role in these scenarios.

Robot Visual Control

François Chaumette
Inria, Rennes, France

Abstract

This article presents the basic concepts of vision-based control, that is, the use of visual data to control the motions of a robotics system. It details the modeling steps allowing the design of kinematics control schemes. Applications are also described.

Keywords

Jacobian; Kinematics; Robot control; Visual ser-voing

Introduction

Visual control, also named visual servoing, refers to the use of computer vision data as input of real-time closed-loop control schemes to control the motion of a dynamic system, a robot typically (Chaumette and Hutchinson 2008; Hutchinson et al. 1996). It can be seen as sensor-based control from a vision sensor and relies on techniques from image processing, computer vision, and control theory.

An iteration of the control scheme consists of the following steps:
Robot Visual Control, Fig. 1 A few images acquired during two visual servoing tasks: on the *top*, pedestrian tracking using a pan-tilt camera; on the *bottom*, control-ling the 6 degrees of freedom of an eye-in-hand system so that an object appears at a particular position in the image (shown in *blue*)

- Acquire an image.
- Extract some useful image measurements.
- Compute the current value of the visual features used as inputs of the control scheme.
- Compute the error between the current and the desired values of the visual features.
- Update the control outputs, which are usually the robot velocity, to regulate that error to zero, i.e., to minimize its norm.

For instance, for the first example depicted on Fig. 1, the image processing part consists in extracting and tracking the center of gravity of the moving people, the visual features are composed of the two Cartesian coordinates of this center of gravity, and the control schemes compute the pan and tilt velocities so that the center of gravity is as near as possible of the image center despite the unknown motion of the people. In the second example where a camera mounted on a six-degrees-of-freedom robot arm is considered, the image measurements are a set of segments that are tracked in the image sequence. From these measurements and the knowledge of the 3D object model, the pose from the camera to the object is estimated and used as visual features. The control scheme now computes the six components of the robot velocity so that this pose reaches a particular desired value corresponding

to the object position depicted in blue on the images.

Basic Theory

Main if not all visual servoing tasks can be expressed as the regulation to zero of an error $\mathbf{e}(t)$ which is defined by

$$\mathbf{e}(t) = \mathbf{s}(\mathbf{m}(\mathbf{r}(t)), \mathbf{a}) - \mathbf{s}^*(t). \qquad (1)$$

The parameters in (1) are defined as follows (Chaumette and Hutchinson 2008). The vector $\mathbf{m}(\mathbf{r}(t))$ is a set of image measurements (e.g., the image coordinates of interest points, or the area, the center of gravity, and other geometric characteristics of an object). These image measurements depend on the pose $\mathbf{r}(t)$ between the camera and the environment. They are used to compute a vector $\mathbf{s}(\mathbf{m}(\mathbf{r}(t)), \mathbf{a})$ of visual features, in which $\mathbf{a}$ is a set of parameters that represent potential additional knowledge about the system (e.g., coarse camera intrinsic parameters or 3D model of objects). The vector $\mathbf{s}^*(t)$ contains the desired value of the features, which can be either constant in the case of a fixed goal or

R

varying if the task consists in following a specified trajectory.

Visual servoing schemes mainly differ in the way that the visual features are designed. As represented on Fig. 2, the two most classical approaches are named image-based visual servoing (IBVS), in which **s** consists of a set of 2D parameters that are directly expressed in the image (Espiau et al. 1992; Weiss et al. 1987), and pose-based visual servoing (PBVS), in which **s** consists of a set of 3D parameters related to the pose between the camera and the target (Weiss et al. 1987; Wilson et al. 1996). In that case, the 3D parameters have to be estimated from the image measurements either through a pose estimation process using the knowledge of the 3D target model, or through a partial pose estimation process using the properties of the epipolar geometry between the current and the desired images, or finally through a triangulation process if a stereovision system is considered. Inside IBVS and PBVS approaches, many possibilities exist depending on the choice of the features. Each choice will induce a particular behavior of the system. There also exist hybrid approaches, named 2-1/2D visual servoing, which combine 2D and 3D parameters in **s** in order to benefit from the advantages of IBVS and PBVS while avoiding their respective drawbacks (Malis et al. 1999).

The design of the control scheme is based on the link between the time variation of the features and the robot control inputs, which are usually the velocity of the robot joints **q**. This relation is given by

$$\dot{\mathbf{s}} = \mathbf{J_s}\,\dot{\mathbf{q}} + \frac{\partial \mathbf{s}}{\partial t} \qquad (2)$$

where $\mathbf{J_s}$ is the features Jacobian matrix, defined from the equation above similarly as the classical robot Jacobian. For an eye-in-hand system (see the left part of Fig. 3), the term $\frac{\partial \mathbf{s}}{\partial t}$ represents the time variation of **s** due to a potential object motion, while for an eye-to-hand system (see the right part of Fig. 3) it represents the time variation of **s** due to a potential sensor motion.

As for the features Jacobian, in the eye-in-hand configuration, it can be decomposed as Chaumette and Hutchinson (2008)
$$\mathbf{J_s} = \mathbf{L_s}\,{}^c\mathbf{V}_n\,\mathbf{J}(\mathbf{q}) \qquad (3)$$
where

- $\mathbf{J}(\mathbf{q})$ is the robot Jacobian such that $\mathbf{v}_n = \mathbf{J}(\mathbf{q})\dot{\mathbf{q}}$ where $\mathbf{v}_n$ is the robot end effector velocity.
- ${}^c\mathbf{V}_n$ is the spatial motion transform matrix from the vision sensor to the end effector. It is given by

$$ {}^c\mathbf{V}_n = \begin{bmatrix} {}^c\mathbf{R}_n & [{}^c\mathbf{t}_n]_\times\,{}^c\mathbf{R}_n \\ \mathbf{0} & {}^c\mathbf{R}_n \end{bmatrix} \qquad (4)$$

where ${}^c\mathbf{R}_n$ and ${}^c\mathbf{t}_n$ are respectively, the rotation matrix and the translation vector between

Robot Visual Control, Fig. 2 If the goal is to move the camera from frame R_c to the desired frame R_{c*}, two main approaches are possible: IBVS on the *left*, where the features **s** and $\mathbf{s}^*$ are expressed in the image, and PBVS on the *right*, where the features **s** and $\mathbf{s}^*$ are related to the pose between the camera and the observed object

Robot Visual Control,
Fig. 3 In visual servoing, the vision sensor can be either mounted on the robot (eye-in-hand configuration) or remote and observing the robot (eye-to-hand configuration). For the same robot motion, the motion produced in the image will be opposite from one configuration to the other
the sensor frame and the end effector frame and where $[^c\mathbf{t}_n]_\times$ is the skew symmetric matrix associated to $^c\mathbf{t}_n$. Matrix $^c\mathbf{V}_n$ is constant when the vision sensor is rigidly attached to the end effector, which is usually the case. Thanks to the robustness of closed-loop control schemes, a coarse approximation of $^c\mathbf{R}_n$ and $^c\mathbf{t}_n$ is sufficient in practice to get an estimation of $^c\mathbf{V}_n$. If needed, an accurate estimation is possible through classical hand-eye calibration methods.

• $\mathbf{L_s}$ is the interaction matrix of $\mathbf{s}$ defined such that $\mathbf{s} = \mathbf{L_s v}$ where $\mathbf{v}$ is the relative velocity between the camera and the environment.

In the eye-to-hand configuration, the features Jacobian $\mathbf{J_s}$ is composed of Chaumette and Hutchinson (2008)

$$\mathbf{J_s} = -\mathbf{L_s} \, ^c\mathbf{V}_f \, ^f\mathbf{V}_n \, \mathbf{J(q)} \qquad (5)$$

where

• $^f\mathbf{V}_n$ is the spatial motion transform matrix from the robot reference frame to the end effector frame. It is known from the robot kinematics model.
• $^c\mathbf{V}_f$ is the spatial motion transform matrix from the camera frame to the reference frame. It is constant as long as the camera does not move. In that case, similarly as for the eye-in-hand configuration, a coarse approximation of $^c\mathbf{R}_f$ and $^c\mathbf{t}_f$ is usually sufficient to get an estimation of $^c\mathbf{V}_f$.

A lot of works have concerned the modeling of the visual features and the determination of the analytical form of the interaction matrix. To give just an example, in the case of an image point with normalized Cartesian coordinates $\mathbf{x} = (x, y)$ and whose 3D corresponding point has depth Z, its interaction matrix is given by Espiau et al. (1992)

$$\mathbf{L_x} = \begin{bmatrix} -1/Z & 0 & x/Z & xy & -(1+x^2) & y \\ 0 & -1/Z & y/Z & 1+y^2 & -xy & -x \end{bmatrix} \qquad (6)$$

where the three first columns contain the elements related to the three components of the translational velocity and where the three last columns contain the elements related to the three components of the rotational velocity.

By just changing the parameters representing the same image point, that is, by using the cylindrical coordinates defined by $\boldsymbol{\gamma} = (\rho, \theta)$ with $\rho = \sqrt{x^2 + y^2}$ and $\theta = \text{Arctan}(y/x)$, the interaction matrix of these parameters has a completely different form (Chaumette and Hutchinson 2008):

$$\mathbf{L_\gamma} = \begin{bmatrix} -c/Z & -s/Z & \rho/Z & (1+\rho^2)s & -(1+\rho^2)c & 0 \\ s/(\rho Z) & -c/(\rho Z) & 0 & c/\rho & s/\rho & -1 \end{bmatrix} \qquad (7)$$

where $c = \cos\theta$ and $s = \sin\theta$. This implies that using the Cartesian coordinates or the cylindrical coordinates as visual features will induce a different behavior, that is, a different robot

trajectory and a different trajectory of the point in the image.

Currently, the analytical form of the interaction matrix is available for most classical geometrical primitives, such as segments, straight lines, ellipses, moments related to planar objects of any shape (Chaumette 2004), and also coordinates of 3D points and pose parameters. Methods also exist to estimate off-line or online a numerical value of the interaction matrix. Omnidirectional vision sensors, the coupling between a camera and structured light, and even 2D echographic probes have also been studied. A large variety of visual features is thus available for many vision sensors.

Once the modeling step has been performed, the design of the control scheme can be quite simple. The most classical control scheme has the following form (Chaumette and Hutchinson 2008):

$$\dot{\mathbf{q}} = -\lambda \widehat{\mathbf{J}_s}^+ (\mathbf{s} - \mathbf{s}^*) + \widehat{\mathbf{J}_s}^+ \frac{\partial \mathbf{s}^*}{\partial t} - \widehat{\mathbf{J}_s}^+ \widehat{\frac{\partial \mathbf{s}}{\partial t}} \quad (8)$$

where λ is a positivive gain tuning the rate of convergence of the system and $\widehat{\mathbf{J}_s}^+$ is the Moore-Penrose pseudo inverse of an approximation or an estimation of the features Jacobian. The exact value of all its elements is indeed generally unknown since it depends of the intrinsic and extrinsic camera parameters, as well as of some 3D parameters such as the depth of the point in Eqs. (6) and (7).

The second term of the control scheme anticipates for the variation of $\mathbf{s}^*$ in the case of a nonconstant desired value. The third term compensates as much as possible a possible target motion in the eye-in-hand case and a possible camera motion in the eye-to-hand case. They are both null in the case of a fixed desired value and a motionless target or camera. They try to remove the tracking error in the other cases.

Following the Lyapunov theory, the stability of the system can be studied (Chaumette and Hutchinson 2008). Generally, visual servoing schemes can be demonstrated to be locally asymptotically stable (i.e., the robot will converge if it starts from a local neighborhood of

the desired pose) if the errors introduced in $\widehat{\mathbf{J}_s}$ are not too strong. Some particular visual servoing schemes can be demonstrated to be globally asymptotically stable (i.e., the robot will converge whatever its initial pose) under similar conditions.

Finally, when the visual features do not constrain all the robot degrees of freedom, it is possible to combine the visual task with supplementary tasks such as, for instance, joint limits avoidance or the visibility constraint (to be sure that the target considered will always remain in the camera field of view). In that case, the redundancy framework can be applied and the error to be regulated to zero has the following form:

$$\mathbf{e} = \widehat{\mathbf{J}_s}^+ (\mathbf{s} - \mathbf{s}^*) + (\mathbf{I} - \widehat{\mathbf{J}_s}^+ \widehat{\mathbf{J}_s}) \, \mathbf{e}_2 \qquad (9)$$

where $(\mathbf{I} - \widehat{\mathbf{J}_s}^+ \widehat{\mathbf{J}_s})$ is a projection operator on the null space of the visual task so that the supplementary task $\mathbf{e}_2$ will be achieved at best under the constraint that the visual task is realized (Espiau et al. 1992). A similar control scheme to (8) is now given by

$$\dot{\mathbf{q}} = -\lambda \, \mathbf{e} - \widehat{\frac{\partial \mathbf{e}}{\partial t}}. \qquad (10)$$

This scheme has for instance been applied for the first example depicted on Fig. 4 where the rotational motion of the mobile robot is controlled by vision, while its translational motion is controlled by the odometry to move at a constant velocity.

Applications

Potential applications of visual servoing are numerous. It can be used as soon as a vision sensor is available and a task is assigned to a dynamic system to control its motion. A non-exhaustive list of examples is (see Fig. 4):

- The control of a pan-tilt-zoom camera, as illustrated in Fig. 1 for the pan-tilt case
- Grasping using a robot arm
Robot Visual Control, Fig. 4 Few applications of visual servoing: navigation of a mobile robot to follow a wall using an omnidirectional vision sensor (*top row*), grasping a ball with a humanoid robot (*middle row*), assembly of MEMS and film of a dialogue within the constraints of a script in animation (*bottom row*)

- Locomotion and dexterous manipulation with a humanoid robot
- Micro- or nano-manipulation of MEMS or biological cells
- Pipe inspection by an underwater autonomous vehicle
- Autonomous navigation of a mobile robot in indoor or outdoor environment
- Aircraft landing
- Autonomous satellite rendezvous
- Biopsy using ultrasound probes or heart motion compensation in medical robotics
- Virtual cinematography in animation

Summary and Future Directions

Visual servoing is basically a nonlinear control problem. Several modeling works have been realized to design visual features so that the control

problem is transformed as much as possible to a linear control problem, leading to better stability properties. On one hand, improvements on this topic are still expected. On the other hand, the design of advanced control schemes, such as optimal control or model predictive control, is another way to make improvements. Then, taking into account dynamic constraints, such as non-holonomic constraints or underactuated systems, also necessitates the design of specific control laws.

Robust Adaptive Control

Anuradha M. Annaswamy
Active-adaptive Control Laboratory, Department of Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, MA, USA

Abstract

Robust adaptive control pertains to the satisfactory behavior of adaptive control systems in the presence of nonparametric perturbations such as disturbances, unmodeled dynamics, and time delays. This article covers the highlights of robust adaptive controllers, methods used, and results obtained. Both methods of achieving robustness, which include modifications in the adaptive law and persistent excitation in the reference input, are presented. In both cases, results obtained for robustness to disturbances and unmodeled dynamics are discussed.

Keywords

Dead zone; Global boundedness; Parameter projection; Persistent excitation; Robustness; s-modification

Introduction

The central problem in adaptive control pertains to regulation and tracking of systems in the presence of parametric uncertainties. The classical adaptive control problem solved in 1980 assumed that the underlying transfer function had unknown parameters, but no other uncertainties. No disturbances, delays, time variations in parameters, or unmodeled dynamics were assumed to be present. Under these ideal conditions, it was shown that an adaptive controller can be designed so that the closed-loop system has bounded signals and that asymptotic regulation and tracking were possible.

With asymptotic regulation and tracking achieved under such ideal conditions, the goal of robust adaptive control was to ensure globally bounded signals in the closed-loop adaptive system when the plant was subjected to a variety of nonparametric perturbations such as external disturbances, time-varying parameters, unmodeled dynamics, and time delays. With adaptation in the control parameters in the ideal case accommodating parametric uncertainties, the approaches developed in robust adaptive control focused on developing solutions in the perturbed case to accommodate nonparametric uncertainties and improving on the classical adaptive controller which either underperformed or even exhibited instability with the introduction of nonparametric perturbations.

We briefly present the adaptive control solutions for the ideal case before proceeding with robust adaptive control.

Classical Adaptive Control

Adaptive Control of Plants with State Feedback

One of the very first problems where stable adaptive control was solved was for the case when states are accessible (Narendra and Kudva 1972), with the plant given by (The argument t is suppressed for the sake of convenience, except for emphasis.)

$$\dot{x}_p = A_p x_p + b\lambda u \qquad (1)$$

where $A_p \in \mathbb{R}^{n \times n}$ and the scalar λ are unknown parameters with b and the sign of λ known and (A_p, b) controllable. An adaptive controller that ensures global boundedness and asymptotic regulation and tracking for such plants is of the form

$$u = \theta_x^T(t)x_p + \theta_r(t)r, \qquad (2)$$

and the adaptive laws for adjusting the unknown parameters are given by

$$\dot{\theta} = -\text{sign}(\lambda)\Gamma\omega b_m^T Pe, \qquad (3)$$

where $\omega = \left[x_p^T, r\right]^T$ and $\theta = \left[\theta_x^T, \theta_r\right]^T$, x_m is the state of a reference model

$$\dot{x}_m = A_m x_m + br \qquad (4)$$

with A_m Hurwitz, and P being the solution of the Lyapunov equation $A_m^T P + PA_m = -Q$, $Q > 0$. The reference model in (4) is to be chosen so that certain matching conditions are satisfied, which are of the form

$$A_p + b\lambda\theta_x^{\star T} = A_m, \qquad \lambda\theta_r^* = 1 \qquad (5)$$

for some $\theta^* = [\theta_x^{*T}, \theta_r^*]^T$. In such a case, the controller in (2) and (3) guarantees stability and ensures that $x(t)$ tracks $x_m(t)$. The underlying Lyapunov function is quadratic in e and the parameter error $\tilde{\theta} = \theta - \theta^*$, given by

$$V = \frac{1}{2}\left(e^T Pe + \lambda\tilde{\theta}^T\Gamma^{-1}\tilde{\theta}\right) \qquad (6)$$

with a negative semi-definite time derivative $\dot{V}$ given by

$$\dot{V} \leq -e^T Qe. \qquad (7)$$

Adaptive Control of Plants with Output Feedback

Consider the *single-input single-output* (SISO) system of equations

$$y(t) = W(s)u(t) \qquad (8)$$

where $u \in \Re$ is the input, $y \in \Re$ the measurable output, and s the differential operator. The transfer function of the plant is parameterized as

$$W(s) \triangleq k_p \frac{Z(s)}{P(s)} \qquad (9)$$

where k_p is a scalar and $Z(s)$ and $P(s)$ are monic polynomials with $\deg(Z(s)) < \deg(P(s))$. The following assumptions will be made throughout:

Assumption 1 $W(s)$ is minimum phase.

Assumption 2 The sign of k_p is known.

Assumption 3 The relative degree n^* and the order of $W(s)$ are known.

The goal is to design a control input u so that the output y in (8) tracks the output y_m of the reference system

$$y_m(t) = W_m(s)r(t) \triangleq k_m \frac{Z_m(s)}{P_m(s)} r(t) \qquad (10)$$

where k_m is a scalar and $Z_m(s)$ and $P_m(s)$ are monic polynomials with $W_m(s)$ relative degree n^*.

The structure of the adaptive controller is now presented:

$$\dot{\omega}_1(t) = \Lambda\omega_1 + b_\lambda u(t) \qquad (11)$$

$$\dot{\omega}_2(t) = \Lambda\omega_2 + b_\lambda y(t) \qquad (12)$$

$$\omega(t) \triangleq [r(t), \; \omega_1^T(t), \; y(t), \; \omega_2^T(t)]^T \qquad (13)$$

$$\theta(t) \triangleq [k(t), \; \theta_1^T(t), \; \theta_0(t), \; \theta_2^T(t)]^T \qquad (14)$$

$$u = \theta^T(t)\omega \qquad (15)$$

where $\Lambda \in \Re^{(n-1)\times(n-1)}$ is Hurwitzx, $b_\lambda \in \Re^{n-1}$, $\omega_1, \omega_2 \in \Re^{n-1}$, and $\theta \in \Re^{2n}$ is an adaptive gain vector with $k(t) \in \Re$, $\theta_1(t) \in \Re^{n-1}$, $\theta_2(t) \in \Re^{n-1}$, and $\theta_0(t) \in \Re$.

The update law for the adaptive parameter differs depending on whether the relative degree of $W_m(s)$ is unity or greater than one and can be described as follows:

$$\dot{\theta}(t) = -\text{sign}(k_p)\Gamma e_y \omega \qquad n^* = 1 \qquad (16)$$

and

$$\dot{\theta}(t) = -\text{sign}(k_p)\Gamma \frac{e_a \zeta}{1 + \zeta^T\zeta} \qquad n^* \geq 2 \qquad (17)$$

where $e_y = y - y_m$, e_a is an augmented error, and ζ is a modified regressor, both of which are determined by the following equations:

$$\zeta = W(s)\omega, \quad \omega = [r, \omega_1^T, y, \omega_2^T]^T, \qquad (18)$$

$$e_2 = \theta^T\zeta - W(s)[\theta^T\omega] \qquad (19)$$

$$e_a = e_y + k_1(t)e_2 \qquad (20)$$

$$\dot{k}_1 = -\frac{e_a e_2}{1 + \zeta^T\zeta} \qquad (21)$$

The results of Narendra and Annaswamy (2005) guarantee that the above adaptive controller in Eqs. (11)–(21) will guarantee that $e_y(t)$ tends to zero as $t \to \infty$ with all signals remaining bounded in both the $n^* = 1$ and $n^* \geq 2$ cases.

Need for Robust Adaptive Control

When a disturbance η is present, the plant dynamics often is of the form

$$\dot{x}_p = A_p x_p + b\lambda(u + \eta(t)) \qquad (22)$$

while the reference model and the controller remain the same as in (4) and (2), respectively. This in turn necessitates new tools for the analysis and synthesis of adaptive systems. The main reason for this is the fact that the standard Lyapunov function candidate given by

$$V = \frac{1}{2}e^T P e + \frac{1}{2}\lambda\tilde{\theta}^T\Gamma^{-1}\tilde{\theta} \qquad (23)$$

together with the parameter adjustment as in (3) yields a time derivative

$$\dot{V} \leq -\frac{1}{2}e^T Q e + k_1\|e\|d_0 \qquad k_1 > 0, \quad (24)$$

where d_0 is an upper bound on the perturbation η. The second term on the right-hand side of (24)

causes $\dot{V}$ to be sign indefinite. This is because V is a function of both e and $\tilde{\theta}$, and therefore, the second term can be large compared to the first with the second argument of V, $\tilde{\theta}$, which can be arbitrary, causing $\dot{V}$ to be sign indefinite. The same property is what caused $\dot{V}$ to be semi-definite in the ideal case. Hence, in this perturbed case, no guarantees of boundedness can be provided. In fact, it can be shown that if $\eta(t)$ is chosen in a particular manner, the closed-loop signals can actually be shown to become unbounded, either in the presence of bounded disturbances (Narendra and Annaswamy 2005) or with unmodeled dynamics (Rohrs et al. 1985). This in turn led to the area of robust adaptive control.

Various approaches that have been developed under the rubric of robust adaptive control can be grouped into two categories. The first of these is related to modifications in the adaptive laws so as to ensure boundedness. These changes consist of modifications in the adaptive law (3) as

$$\dot{\theta} = -\Gamma \omega(t) b_m^T P e - \sigma g(\theta, e) \qquad (25)$$

The problem then reduces to finding a suitable $g(\theta, e)$. This is discussed in detail in the next sec-

tion. The second approach used in adaptive control pertains to the use of a persistently exciting reference signal r. The latter ensures parameter convergence of the adaptive system and therefore exponential stability. This in turn ensures robustness of the overall system. These details are addressed in section "Robust Adaptive Control with Persistently Exciting Reference Input."

Robust Adaptive Control with Modifications in the Adaptive Law

Robustness to Bounded Disturbances
When a bounded input disturbance η is present, the plant dynamics is changed as

$$\dot{x}_p = A_p x_p + b\lambda(u + \eta(t)), \qquad (26)$$

while the reference model and the controller remain the same as in (4) and (2), respectively. As mentioned above, a modification to the adaptive law as in (25) is needed. Over the years, different choices have been suggested for the nonlinear function $g(\theta, e)$. For example, these are chosen as

$$g(\theta, e) = \begin{cases} \theta & \text{Ioannou and Sun (2013)} \\ ||e||\theta & \text{Narendra and Annaswamy (2005)} \\ \theta \left(1 - \frac{||\theta||}{\theta_{\max}}\right)^2 & \text{Kreisselmeier and Narendra (1982)} \end{cases} \qquad (27)$$

where $\theta_{\max}$ is a known bound on the parameter θ. (One can choose to set σ to zero if $\|\theta\| \le \theta_{\max}$, as is done in Ioannou and Sun (2013), Tsakalis and Ioannou (1987) and many other references in the literature.) An alternate approach that is different from (25) is to not have an additive term $g(\cdot, \dot{})$ but rather set $\dot{\theta} = 0$ whenever the error e is small in some sense. Such a dead zone approach was suggested, for example, in Egardt (1979) and Peterson and Narendra (1982). It can be shown that each one of these choices leads to boundedness, which is described below. Without loss of generality, we assume that $\lambda > 0$.

With the same Lyapunov function candidate as in (23), its time derivative now becomes

$$\dot{V} \le -\frac{1}{2} e^T Q e + k_1 \|e\| \|\eta\|$$
$$\quad - \frac{1}{2} \|\tilde{\theta}\|^T g(\theta, e), \qquad k_1 > 0 \qquad (28)$$

The property of $g(.,.)$, together with the fact that η is bounded, ensures that $\dot{V} < 0$ outside a compact set Ω in the $(e, \tilde{\theta})$ space. This ensures global boundedness of both e and $\tilde{\theta}$. Boundedness of x_p follows.

In all of the above methods, the idea behind adding the term $g(e, \theta)$ is this: the parameter θ can drift away from the correct direction due to the term $k_1 \|e\| \|\eta\|$, and the construction of $g(e, \theta)$ is such that it counteracts this drift and keeps the parameter in check, by adding a negative quadratic term in $\tilde{\theta}$. The boundedness of both e and θ is simultaneously assured in the above since V has a time derivative $\dot{V}$ that is nonpositive outside a compact set in the $(e, \tilde{\theta})$ space. It should be noted however that this was possible to a large extent because η was bounded, and as a result, the sign-indefinite term remained linear in $\|e\|$.

An alternative procedure, originally proposed in Pomet and Praly (1992) and revised and refined in Khalil (2001) and Lavretsky (2010), proceeds in a slightly different manner. Here, the boundedness of θ is first established, independent of the error equation. It should be noted that a similar approach is adopted in the context of output feedback in plants with higher relative degree by using normalization and an augmented error approach (Narendra and Annaswamy 2005). In Khalil (2001) and Lavretsky (2010), no normalization is used but a projection algorithm. This is described below.

The projection algorithm for adjusting the parameter θ is given by

$$\dot{\theta} = \mathrm{Proj}(\theta, y), \qquad (29)$$

where

$$\mathrm{Proj}(\theta, y) = \begin{cases} y - \dfrac{\nabla f(\theta)(\nabla f(\theta))^T}{\|\nabla f(\theta)\|^2} y f(\theta) \\ \qquad \text{if } [f(\theta) > 0 \bigwedge y^T \nabla f(\theta) > 0] \\ y \qquad \text{otherwise} \end{cases} \qquad (30)$$

$$y = -e^T P b \omega \qquad (31)$$

$$f(\theta) = \frac{\| \theta \|^2 - \theta_{\max}'^2}{\varepsilon^2 + 2\varepsilon \theta_{\max}'} \qquad (32)$$

where $\theta_{\max}'$ and ε are arbitrary positive constants, and Ω_0 and Ω_1 are defined as

$$\begin{aligned} \Omega_0 &= \left\{ \theta \in \mathbb{R}^n | f(\theta) \leq 0 \right\} \\ \Omega_1 &= \left\{ \theta \in \mathbb{R}^n | f(\theta) \leq 1 \right\}. \end{aligned} \qquad (33)$$

From the above relations, one can show that

$$\theta(0) \in \Omega_0 \implies \theta(t) \in \Omega_1.$$

In addition,

$$\theta_{\max}' = \max_{\theta \in \Omega_0} (\|\theta\|), \quad \theta_{\max} = \max_{\theta \in \Omega_1} (\|\theta\|) \quad (34)$$

where $\theta_{\max} = \theta_{\max}' + \varepsilon$ (Matsutani et al. 2011).

Robustness to Unmodeled Dynamics

One of the major observations in the early eighties was the stark difference between the system signals in the ideal adaptive system and the perturbed adaptive system when the perturbation was due to a commonly present unmodeled dynamics such as those of an actuator used for control implementation. Among other references, the publication in Rohrs et al. (1985) pointed out the fact that when an adaptive controller prescribed for a first-order plant is evaluated with unmodeled dynamics present, instability occurs readily and for a wide range of command signals. A number of solutions have been suggested to alleviate this instability and form the subject matter of this section.

We consider the plant in (26) with an additional unmodeled dynamics so that

$$\begin{aligned} \dot{x}_p &= A_p x_p + b \lambda v \\ \dot{x}_\eta &= A_\eta x_\eta + b_\eta u, \quad v = \tilde{c}_\eta^T x_\eta. \end{aligned} \qquad (35)$$

where A_η is a Hurwitz matrix. If $\eta = v - u$, then the plant dynamics can be rewritten as

$$\dot{x}_p = A_p x_p + b\lambda(u + \eta) \tag{36}$$

Unlike the bounded disturbance case, no upper bound d_0 can be assumed to exist as η is a state-dependent disturbance. It is this that causes a huge difference between deriving boundedness in section "Robustness to Bounded Disturbances" and here in section "Robustness to Unmodeled Dynamics." Significant effort has been extended in the adaptive control community in this regard. These results fall into two categories (i) that assure global boundedness for a narrow class of unmodeled dynamics and (ii) that assure semi-global boundedness for a slightly larger class of unmodeled dynamics. More recently, some results have been obtained that are able to establish global boundedness with minimal restrictions on the unmodeled dynamics. In what follows, we give examples of each of the above two cases as well as the recent results.

Global Boundedness in the Presence of a Small Class of Unmodeled Dynamics

For the plant in (26), under assumptions in (5), the plant can be rewritten as

$$\dot{x} = A_m x + b\lambda(u + \theta_x^{*T} x + \eta) \tag{37}$$

where λ and θ_x^* are unknown, A_m and b are known, and $\eta = v - u$ whose state-space representation can be shown to be of the form

$$\dot{x}_\eta = A_\eta x_\eta + b_\eta u, \quad \eta = c_\eta^T x_\eta \tag{38}$$

for some vector c_η.

For a class of unmodeled dynamics $\{c_\eta, A_\eta, b_\eta\}$, if the control input in (2) and the projection algorithm in (29) with y and $f(\theta)$ chosen as in (31) and (32) are used, one can guarantee boundedness. In particular, if the inequality

$$k\theta_{x,\max} \lambda_{\max}\left(\frac{b_0}{\sigma_{A_\eta}}\right) < 1 \tag{39}$$

is satisfied, where b_0 is an upper bound on $||b_\eta||$ and σ_A denotes the singular value of the matrix A, then boundedness follows. That is, robustness of adaptive controllers can be ensured if the unmodeled dynamics is fast and their zeros are restricted in some sense.

A specific example of such an unmodeled dynamics is given by

$$c_\eta^T (sI - A_\eta)^{-1} b_\eta = \frac{-2\mu s}{1 + \mu s}. \tag{40}$$

Global Boundedness for a Large Class of Unmodeled Dynamics: A First-Order Example

A different approach can be taken for the problem of unmodeled dynamics which allows a global result, for a class of adaptive systems (Hussain et al. 2013). The main idea here is to use the projection algorithm and use properties of adaptive systems in conjunction with linear time-varying systems. This is presented in this section using a first-order plant.

We consider the control of

$$\dot{x}_p(t) = a_p x_p(t) + k_p v(t) \tag{41}$$

where a_p is unknown and k_p is known. It is assumed that $|a_p| \leq \bar{a}$, where $\bar{a}$ is a known positive constant. The unmodeled dynamics is given by (38) with

$$G_\eta(s) \triangleq c_\eta^T (sI_{n\times n} - A_\eta)^{-1} b_\eta. \tag{42}$$

The goal is to design the control input such that $x_p(t)$ follows $x_m(t)$ which is specified by the reference model

$$\dot{x}_m(t) = a_m x_m(t) + k_m r(t) \tag{43}$$

where $a_m < 0$ and $r(t)$ is the reference input. The adaptive controller we propose is given by

$$u(t) = \theta(t)x_p(t) + \frac{k_m}{k_p} r(t) \tag{44}$$

where the parameter $\theta(t)$ is updated using a projection algorithm given by

$$\dot{\theta}(t) = \gamma \,\mathrm{Proj}(\theta(t), -x_p(t)(x_p(t) - x_m(t))),$$
$$\gamma > 0 \qquad\qquad (45)$$

and

$$\mathrm{Proj}(\theta, y) = \begin{cases} \dfrac{\theta_{\max}^2 - \theta^2}{\theta_{\max}^2 - \theta_{\max}'^2}\, y & [\theta \in \Omega_A,\ y\theta > 0] \\[3em] y & \text{otherwise} \end{cases}$$
$$(46)$$

$$\Omega_0 = \{\theta \in \mathbb{R}^1 \mid -\theta_{\max}' \le \theta \le \theta_{\max}'\}$$
$$\Omega_1 = \{\theta \in \mathbb{R}^1 \mid -\theta_{\max} \le \theta \le \theta_{\max}\} \qquad (47)$$
$$\Omega_A = \Omega_1 \backslash \Omega_0$$

with positive constants $\theta_{\max}'$ and $\theta_{\max}$ given by

$$\theta_{\max}' > \frac{\bar{a} + |a_m|}{k_p}, \qquad \theta_{\max} = \theta_{\max}' + \varepsilon_0, \quad (48)$$

where ε_0 is an arbitrary constant. It can be shown that if $\theta_{\max}$ is chosen as in (48), then the closed

adaptive system specified by Eqs. (41)–(48) always has guaranteed bounded solutions for a class of unmodeled dynamics $G_\eta(s)$. There is an optimal value of ε_0, however, for which a largest class of $G_\eta(s)$ can be found.

It should be noted that in the Rohrs example in Rohrs et al. (1985), the plant is first order, with $a_p = -1$, and

$$G_\eta = \frac{w_n^2}{s^2 + 2\zeta\omega_n s + \omega_n^2}, \qquad (49)$$

for $\zeta = 1$, $\omega_n = 15$. It is easy to show that for these values of ζ and ω_n, if $\theta_{\max} = 17$, then Eq. (48) is satisfied and that the closed-loop system is robust to G_η.

In general, for a first-order plant as in (41), it can be shown that the adaptive system is robust for G_η for all (ζ, ω_n) that satisfy the following inequalities for all $|a_p| \le \bar{a}$:

$$-a_p\zeta^2 + f(a_p, \omega_n)\zeta - \frac{k_p\theta_{\max}}{4} > 0$$
$$(50)$$
$$\omega_n > \omega_{n_{\min}}$$

where

$$f(a_p, \omega_n) = \frac{a_p^2 + \omega_n^2}{2\omega_n}$$

$$w_{n_{\min}} = \max\left(\frac{\bar{a}}{2\zeta}, 2\zeta\bar{a}, \sqrt{\bar{a}k_p\theta_{\max}}\left\{1 + \sqrt{1 - \frac{\bar{a}}{k_p\theta_{\max}}}\right\}\right) \qquad (51)$$

When a time delay τ is present in the plant to be controlled, the plant under consideration can be represented as in (37) where

$$\eta(t) = u(t - \tau) - u(t)$$

Similar results of global boundedness can be derived in this case as well (Matsutani 2013; Matsutani et al. 2012, 2013).

Robust Adaptive Control with Persistently Exciting Reference Input

We return to the plant in (26) with the control input as in (2) and the adaptive law as in (3).

When $\eta(t)$ is bounded with a finite upper bound d_0, it can be shown that no modifications are necessary in the adaptive law to ensure boundedness if the reference input is persistently exciting. It can be shown that if the reference input $r(t)$ is such that the vector ω^* defined as $\omega^* = [x_m^T, r]^T$ is persistently exciting with

$$\left| \frac{1}{T} \int_t^{t+T} \omega^{*T}(\tau)w\,d\tau \right| \ge kd_0 \quad \forall\, t \ge t_0, \forall w \in \mathbb{R}^n$$

where k, T are finite constants and w is a unit vector, then the adaptive system is well behaved,

i.e., has globally bounded solutions (Narendra and Annaswamy 2005).

An alternative approach for achieving robustness has been addressed in Anderson et al. (1986) that addresses local stability in the presence of persistently exciting signals. The starting point for this investigation is (35) but when all states are not accessible. Assuming that an output $y = c_p^T x_p$ is measurable and a controller as in (11)–(15) and a reference model as in (10) are used, the underlying error equation can be written as

$$e_1 = \overline{W}_m(s)\left(\tilde{\theta}^\top \omega + \overline{v}\right) \qquad (52)$$

where $\overline{W}_m(s)$ is asymptotically stable, $\tilde{\theta}$ is the parameter error vector, and $\overline{v}$ is the effect of the unmodeled dynamics η at the output. Suppose the standard adaptive law is used, and as a first step the perturbation $\overline{v}$ is ignored, the underlying error equation and the adaptive law are given by

$$e_1 = \overline{W}_m(s)\tilde{\theta}^\top \omega \qquad (53)$$

$$\dot{\tilde{\theta}} = -\mu e_1 \omega, \quad \mu > 0. \qquad (54)$$

If the origin in the $(e_1, \tilde{\theta})$ space of (53) and (54) is exponentially stable, all solutions of (52) are bounded for sufficiently small initial conditions and $\overline{v}(t)$. Therefore, the question that is of interest is the set of conditions of persistent excitation that will assure such an exponential stability. This is addressed in Anderson et al. (1986). The underlying tool is the Method of Averaging (Arnold 1982; Hale 1969; Krylov and Bogoliuboff 1943) used in the study of nonlinear oscillations and addresses the stability property of the differential equation

$$\dot{x} = \mu f(x, t, \mu), \qquad x(0) = x_0 \qquad (55)$$

where μ is a small parameter. By a process of averaging, the nonautonomous system in (55) is approximated by an autonomous differential equation in x_{av}, an averaged value of x. This autonomous system, which is easier to analyze, can be used to derive stability properties of (55).

In order to use the method of averaging for robust adaptive control, we write Eqs. (53) and (54) as

$$\begin{bmatrix} \dot{e} \\ \dot{\tilde{\theta}} \end{bmatrix} = \begin{bmatrix} A & b\omega^\top \\ -\mu\omega h^\top & 0 \end{bmatrix} \begin{bmatrix} e \\ \tilde{\theta} \end{bmatrix} \qquad (56)$$

Theorem 1 *Let $\omega(t)$ be bounded, almost periodic, and persistently exciting. Then there exists a $c^* > 0$ such that for all $\mu \in (0, c^*]$, the origin of (56) is exponentially stable if*

$$\Re\left[\lambda_i\left(\int_0^T \omega(t)\bar{W}_m(s)\omega^\top(t)dt\right)\right] > 0,$$
$$\forall i = 1, \ldots, n \qquad (57)$$

and is unstable if

$$\Re\left[\lambda_j\left(\int_0^T \omega(t)\bar{W}_m(s)\omega^\top(t)dt\right)\right] < 0,$$
$$\textit{for some } j = 1, \ldots, n \qquad (58)$$

In Kokotovic et al. (1985), it is further shown that $\omega(t)$ can be expressed at $\omega(t) = \sum_{k=-\infty}^{\infty} \Omega(iv_k)\exp(iv_k t)$ and the inequality in (57) can be satisfied if the condition

$$\sum_{k=-\infty}^{\infty} \Re\left[\bar{W}_m(iv_k)\right]\Re\left[\Omega(iv_k)\bar{\Omega}^\top(iv_k)\right] > 0 \qquad (59)$$

is satisfied, where $\bar{\Omega}(iv_k)$ is the complex conjugate of $\Omega(iv_k)$. Given a general transfer function $\bar{W}_m(s)$, there exists a large class of functions ω that satisfies (59), even when $\bar{W}_m(s)$ is not SPR.

ω in Theorem 1 is not an independent variable but rather an internal variable of the nonlinear system in (56). Hence, it cannot be shown to be bounded or persistently exciting. If ω_* represents the signal corresponding to ω in the reference model, it can be made to satisfy (57) by the proper choice of the reference input. Expressing $\omega = \omega_* + \omega_e$, ω will also be bounded, persistently exciting, and satisfy (57) if ω_e is small. This can be achieved by choosing the initial conditions $e(t_0)$ and $\tilde{\theta}(t_0)$ in (56) to be sufficiently small.

R

The conditions of Theorem 1 are then verified, and for a sufficiently small μ, exponential stability of the origin of (56) follows.

Theorem 1 provides conditions for exponential stability and instability when the solutions of the adaptive system are sufficiently close to the tuned solutions. These are very valuable in understanding the stability and instability mechanisms peculiar to adaptive control in the presence of different types of perturbations. Many of these results have been summarized and presented in a unified fashion in Anderson et al. (1986).

Robust Control in Gap Metric

Li Qiu
Hong Kong University of Science and Technology, Hong Kong SAR, China

Abstract

Robust control needs to start with a model of system uncertainty. What is a good uncertainty model? First it needs to capture the possible system perturbations and uncertainties. Second it needs to be mathematically tractable. The gap metric was introduced by Zames and El-Sakkary for this purpose. Its study climaxed in an award-winning paper by Georgiou and Smith. A modified gap, called the ν-gap, was later discovered by

Vinnicombe and was shown to have advantages. With these metrics in hand, robust stabilization issues can be nicely addressed.

Keywords

Gap metric; H-infinity control; ν-gap metric; Robust stabilization; Uncertain system

Introduction

The gap is rooted in mathematical literature for the purpose of measuring the distance between unbounded operators (Kato 1976). It is introduced to control theory by Zames and El-Sakkary (1980) to measure the distance between systems and subsequently to model an uncertain system, with the recognition that a possibly unstable system is simply a possibly unbounded operator. Here only continuous-time systems will be treated. Discrete-time systems can be treated in an analogous way. Let us identify a linear time-invariant (LTI) system with its transfer function. The set of m-input p-output finite-dimensional LTI systems is then identified with the set $\mathcal{R}^{p \times m}$ of $p \times m$ real rational matrices. Such a system can be considered as a linear operator from input space $\mathcal{H}_2^m$ to output space $\mathcal{H}_2^p$, defined by the input-output relation $y = Pu$. Here $\mathcal{H}_2$ is the collection of all bounded-energy signals $x(s)$ satisfying

$$\|x\|_2 := \sup_{\sigma > 0} \left(\frac{1}{2\pi} \int_{-\infty}^{\infty} |x(\sigma + j\omega)|^2 d\omega \right)^{1/2}$$
$$< \infty.$$

This operator is possibly unbounded since for an input $u \in \mathcal{H}_2^m$, the corresponding output $y = Pu$ is not necessarily in $\mathcal{H}_2^p$. It is bounded if and only if P is stable, i.e., if and only if $P \in \mathcal{RH}_\infty^{p \times m}$, the set of $p \times m$ real rational matrices bounded over $\mathrm{Re}\, s > 0$. In this case, the induced operator norm is the $\mathcal{H}_\infty$ norm of P:

$$\|P\|_\infty = \sup_{\mathrm{Re}\, s > 0} \bar{\sigma}[P(s)] = \sup_{\omega \in \mathbb{R}} \bar{\sigma}[P(j\omega)].$$

No matter whether or not P is stable, we define the graph of P as

$$\mathcal{G}_P = \left\{ \begin{bmatrix} u \\ y \end{bmatrix} \in \mathcal{H}_2^{m+p} : y = Pu \right\},$$

i.e., the graph is the set of all finite energy input-output pairs. It is easy to see that $\mathcal{G}_P$ is a linear subspace of $\mathcal{H}_2^{m+p}$ and a little more effort shows that it is closed. Hence it uniquely corresponds to a bounded linear operator on $\mathcal{H}_2^{m+p}$, called the orthogonal projection onto $\mathcal{G}_P$, denoted by $\Pi_{\mathcal{G}_P}$. Now with two systems $P_1, P_2 \in \mathcal{R}^{p \times m}$, the gap in between is defined as

$$\delta(P_1, P_2) = \|\Pi_{\mathcal{G}_{P_1}} - \Pi_{\mathcal{G}_{P_2}}\|.$$

That the gap is a metric in $\mathcal{R}^{p \times m}$ follows from the fact that the induced operator norm used above defines a metric on the set of all orthogonal projections.

With the gap between two systems, an uncertain system described by the gap is simply a gap metric ball with a center P, called the nominal system, and a radius r, qualifying the amount of uncertainty:

$$\mathcal{B}(P, r) = \{\tilde{P} \in \mathcal{R}^{p \times m} : \delta(\tilde{P}, P) < r\}.$$

Gap Computation and Robust Stabilization

With the basic definitions constructed above, the following questions are then asked:

Computation: How can the gap between two systems be computed?

Analysis: How much stability robustness does a stable feedback system have against gap uncertainty in the plant or in both the plant and the controller?

Synthesis: How can a feedback controller be designed so that the feedback system has optimal robustness against gap uncertainty?

For the question on computation, it is rather easy to see that if P_1 and P_2 are static, also said to be memoryless, systems, i.e., $P_1(s) = K_1$ and $P_2(s) = K_2$, then

R

$$\delta(P_1, P_2) = \bar{\sigma}[(I + K_1 K_1')^{-1/2}$$
$$(K_1 - K_2)(I + K_2' K_2)^{-1/2}].$$

In the single-input-single-output case, this is exactly the chordal distance between two numbers K_1 and K_2. Hence the expression above generalizes the chordal distance between two complex numbers to constant matrices. What if P_1 and P_2 are dynamic systems? It is not until Georgiou (1988) when the computation of the gap was settled by using the coprime factorization.

For each $P \in \mathcal{R}^{p \times m}$, there are

$$\begin{bmatrix} \tilde{V} & -\tilde{U} \\ -\tilde{N} & \tilde{M} \end{bmatrix}, \begin{bmatrix} M & U \\ N & V \end{bmatrix} \in \mathcal{RH}_\infty^{(m+p) \times (m+p)}$$

such that $P = NM^{-1} = \tilde{M}^{-1}\tilde{N}$ and

$$\begin{bmatrix} \tilde{V} & -\tilde{U} \\ -\tilde{N} & \tilde{M} \end{bmatrix} \begin{bmatrix} M & U \\ N & V \end{bmatrix} = \begin{bmatrix} I & 0 \\ 0 & I \end{bmatrix}.$$

These matrices are said to give a doubly coprime factorization of P. Also $P = NM^{-1}$ and $P = \tilde{M}^{-1}\tilde{N}$ are said to be right and left coprime factorizations, respectively. In the doubly coprime factorization, we can further require

$$M^T(-s)M(s) + N^T(-s)N(s) = I \text{ and}$$
$$\tilde{M}(s)\tilde{M}^T(s) + \tilde{M}(s)\tilde{M}^T(s) = I.$$

In this case, the coprime factorizations are said to be normalized.

Theorem 1 (Computation of the gap) *Let $P_i = N_i M_i^{-1}, i = 1, 2$, be normalized right coprime factorizations. Then*

$$\delta(P_1, P_2) = \max \left\{ \inf_{Q \in \mathcal{RH}_\infty^{m \times m}} \left\| \begin{bmatrix} M_1 \\ N_1 \end{bmatrix} - \begin{bmatrix} M_2 \\ N_2 \end{bmatrix} Q \right\|_\infty, \inf_{Q \in \mathcal{RH}_\infty^{m \times m}} \left\| \begin{bmatrix} M_2 \\ N_2 \end{bmatrix} - \begin{bmatrix} M_1 \\ N_1 \end{bmatrix} Q \right\|_\infty \right\}.$$

The problems of finding the two infima above are $\mathcal{H}_\infty$ model-matching problems, special forms of $\mathcal{H}_\infty$ control problems. See article ▸ Optimal Control via Factorization and Model Matching and article ▸ H-Infinity Control in this encyclopedia. In principle, they can be solved using the standard ways.

The analysis and synthesis questions are satisfactorily answered by Georgiou and Smith (1990). Let us consider the feedback system shown in Fig. 1.

Such a feedback system is denoted by a plant and controller pair or simply a feedback pair $(P, C) \in \mathcal{R}^{p \times m} \times \mathcal{R}^{m \times p}$. This closed-loop system is stable if the transfer matrix from $\begin{bmatrix} w_1 \\ -w_2 \end{bmatrix}$ to $\begin{bmatrix} u_1 \\ y_2 \end{bmatrix}$, nicknamed the Gang of Four matrix,

$$GoF = \begin{bmatrix} (I + PC)^{-1} & (I + PC)^{-1}C \\ C(I + PC)^{-1} & P(I + PC)^{-1}C \end{bmatrix}$$
$$= \begin{bmatrix} I \\ P \end{bmatrix}(I + PC)^{-1}[I \ C]$$

is stable, i.e., belongs to $\mathcal{RH}_\infty$.

Theorem 2 (Stability margin) *Assume (P, C) form a stable closed-loop system. All feedback systems $(\tilde{P}, C)$ with $\tilde{P} \in \mathcal{B}(P, r)$ are stable if and only if $r \leq \|GoF\|_\infty^{-1}$.*

It follows from Theorem 2 that $\|GoF\|_\infty^{-1}$ is the stability margin of the closed-loop system in Fig. 1. The natural design problem is then to design a controller C for a given P such that $\|GoF\|_\infty^{-1}$ is maximized or equivalently $\|GoF\|_\infty$ is minimized. Such a problem again is an $\mathcal{H}_\infty$ control problem, which is the topic of article ▸ H-Infinity Control in this encyclopedia. It is realized by Georgiou and Smith (1990) that this particular $\mathcal{H}_\infty$ control problem has some unique features. Let P have a normalized doubly coprime factorization and let

$$R(s) = M^T(-s)U(s) + N^T(-s)V(s).$$

Then
Robust Control in Gap Metric, Fig. 1 An uncertain feedback system

$$\inf_C \|GoF\|_\infty = \left(1 + \inf_{Q \in \mathcal{RH}_\infty^{m \times p}} \|R - Q\|_\infty\right)^{1/2}.$$

The minimization over Q above is a one-block $\mathcal{H}_\infty$ model-matching problem. It can be solved rather easily, much more easily than the $\mathcal{H}_\infty$ model-matching problem arising in the computation of gap. After finding an optimal Q, an optimal controller is obtained as

$$C = -(U - MQ)(V - NQ)^{-1}.$$

Qiu and Davison (1992a) extended Theorem 2 to the case when both the plant and controller are subject to uncertainty.

Theorem 3 (The arcsin theorem) *Assume (P, C) form a stable closed-loop system. All*

feedback systems $(\tilde{P}, \tilde{C}) \in \mathcal{B}(P, r_P) \times \mathcal{B}(C, r_C)$ are stable if and only if

$$\arcsin r_P + \arcsin r_C \leq \arcsin \|GoF\|_\infty^{-1}.$$

This theorem further strengthens the role of $\|GoF\|_\infty^{-1}$ as the stability robustness of the feedback system (P, C).

The ν-Gap

Partly because of the lack of efficient ways in computing the gap, there were efforts in seeking other metrics on $\mathcal{R}^{p \times m}$ with better numerical and analytical properties. Several such metrics were proposed, including the graph metric by Vidyasagar (1984), pointwise gap metric by Qiu and Davison (1992b), and ν-gap metric by Vinnicombe (1993). The winner is the ν-gap which is defined by ingeniously exploring the special structures and properties of rational matrices in $\mathcal{R}^{p \times m}$. For $P_1, P_2 \in \mathcal{R}^{p \times m}$, let $P_i = N_i M_i^{-1}, i = 1, 2$, be normalized right coprime factorizations. Define the ν-gap metric as

$$\delta_\nu(P_1, P_2) = \sup_{\omega \in \mathbb{R}} \bar{\sigma} \left\{[I + P_1(j\omega)P_1(j\omega)^*]^{-1/2}[P_1(j\omega) - P_2(j\omega)][I + P_2(j\omega)^* P_2(j\omega)]^{-1/2}\right\}$$

if $\det[M_2^T(-s)M_1(s) + N_2^T(-s)N_1(s)]$ has equal number of unstable poles and zeros and $\delta_\nu(P_1, P_2) = 1$ otherwise. Apparently ν-gap is easier to compute than the gap. When the pole-zero number condition is satisfied, the ν-gap is the peak of the chordal distance between the system frequency responses. The ν-gap is no greater than the gap, i.e.,

$$\delta_\nu(P_1, P_2) \leq \delta(P_1, P_2).$$

Hence the ν-gap ball

$$\mathcal{B}_\nu(P, r) = \{\tilde{P} \in \mathcal{R}^{p \times m} : \delta_\nu(\tilde{P}, P) < r\}$$

is a superset of the gap ball with the same center and radius. Theorems 2 and 3 can be restated

with the gap balls $\mathcal{B}$ replaced by the new gap balls $\mathcal{B}_\nu$. Consequently the restated Theorems 2 and 3 are less conservative than the original versions for the gap. The optimal robust stabilization problems for the gap and the ν-gap are the same: design C to maximizing $\|GoF\|_\infty^{-1}$ for a given P.

Summary and Future Directions

The gap, as well as the ν-gap, and the associated robust control theory can be extended to infinite dimensional systems as in Georgiou and Smith (1992) and Ball and Sasane (2012), time-varying systems as in Foias, Georgiou, and Smith et al.

(1993) and Feintuch (1998), and even nonlinear systems as in Georgiou and Smith (1997), Anderson et al. (2002), James et al. (2005), and Bian and French (2005), in varying degrees. There are still research opportunities in these extensions. The use of normalized coprime factorizations seems to be an obstacle in these extensions.

For a plant P, the controller optimizing $\|GoF\|_\infty$ is not always a good controller. This gives another example where "optimal" is not always equal to "good." One reason is that the actual plant uncertainty cannot necessarily be well described by a gap ball or a ν-gap ball. Another reason is that performance issues other than the stability robustness, such as tracking and disturbance rejection, are not taken into account in the optimization. The actual plant uncertainty might be better described by a gap ball centered at a frequency-shaped plant $\tilde{P} = W_o P W_i$ where W_i and W_o are real rational weighting matrices which can also be chosen to address tracking and disturbance rejection requirements. In this case, an optimal controller $\tilde{C}$ can then be designed to optimize the GoF matrix corresponding the shaped plant $\tilde{P}$. Finally $C = W_i \tilde{C} W_o$ is used as a designed controller for the original plant P. With the proper choice of W_i and W_o, it is more likely that a good controller will result. This loop-shaping design method was proposed in McFarlane and Glover (1992) and further developed in Vinnicombe (2001).

In the process of obtaining the arcsin theorem, it has been realized that the gap and even more so the ν-gap are closely related to the canonical angles between linear subspaces. In fact the gap is the sin of the largest canonical angle between certain subspaces and the largest canonical angle itself is also a metric, a better one in some geometric sense. For the latest development on canonical angles, see Qiu et al. (2008) and Zhang and Qiu (2010).

In addition to the effort in deepening and expanding the notion of gap and its use in robust control, there is also effort in making it more accessible and more closely related to classical frequency response analysis; see Qiu and Zhou (2013). It again appears that the use of coprime factorizations in the current theory is hindering this effort. Hence, circumventing the use of coprime factorizations, normalized or not, in the development of the gap would help its extension and popularization.

Recommended Reading

The most authoritative work on gap, ν-gap and the associated robust stabilization theory is the comprehensive monograph Vinnicombe (2001). This theory is inherently an input-output frequency domain theory. However many related computations, such as those of doubly normalized coprime factorizations, $\mathcal{H}_\infty$ model matching, and the optimal controller synthesis, can be done using state-space formulas and further using MATLAB programs. Vinnicombe (2001) contains a list of such state-space formulas. This theory provides a good example of the once popular and successful philosophy behind the linear multivariable control theory: thinking in terms of transfer functions and computing in term of state-space equations.

The system and control background needed to understand and study the gap, the ν-gap, and robust stabilization, in particular the coprime factorization and frequency domain stabilization theory, can be found in Vidyasagar (1985).

The book Zhou and Doyle (1998) also contains considerable content on gap based robust control.

Robust Control of Infinite Dimensional Systems

Hitay Özbay
Department of Electrical and Electronics
Engineering, Bilkent University, Ankara, Turkey

Abstract

Basic robust control problems are studied for the feedback systems where the underlying plant model is infinite dimensional. The $\mathcal{H}_\infty$ optimal controller formula is given for the mixed sensitivity minimization problem with rational weights. Key steps of the numerical computations required to determine the controller parameters are illustrated with an example where the plant model include time delay terms.
Keywords

Coprime factorizations; Direct design methods; Inner-outer factorizations

Introduction

Robust control deals with the feedback system shown in Fig. 1, where P_Δ represents the uncertain physical plant and C is a fixed controller to be designed.

Here, it is assumed that the controller and the plant are linear time invariant (LTI) systems and

Robust Control of Infinite Dimensional Systems, Fig. 1 Feedback system $\mathcal{F}(C, P_\Delta)$ with fixed controller C and uncertain plant P_Δ

they are represented by their transfer functions. Furthermore, P_Δ satisfies the following conditions:

$$P_\Delta(s) = P(s) + \Delta(s)$$

where P is the nominal plant model, with $P(s)$ and $P_\Delta(s)$ having the same number of poles in $\mathbb{C}_+$; and there is a known uncertainty bound $W(s)$ satisfying

$$|\Delta(j\omega)| < |W(j\omega)| \quad \forall\, \omega \in \mathbb{R}.$$

Definition 1 All P_Δ satisfying the above conditions are said to be in *the set of uncertain plants* $\mathcal{P}$, which is characterized by the given functions $P(s)$ and $W(s)$.

Depending on physical system modeling, other forms of uncertainty representations can be more convenient than the additive unstructured uncertainty model taken here; see, e.g., Doyle et al. (1992), Özbay (2000), and Zhou et al. (1996) for the examples of multiplicative, coprime factor, parametric, and structured uncertainty descriptions. Note that for notational convenience and simplicity of the presentation, single-input-single-output (SISO) plants are considered here; for extensions to multi-input-multi-output (MIMO) plants, see, e.g., Curtain and Zwart (1995).

When the plant under consideration is infinite dimensional, the transfer function $P(s)$ is irrational, i.e., it cannot be expressed as a ratio of two polynomials (it does not admit a finite-dimensional state-space representation). Typical examples of such systems are spatially distributed parameter systems modeled by partial differential equations, fractional-order systems, and systems with time delays. The reader is referred to Curtain and Morris (2009) for examples of transfer functions of distributed parameter systems. There are many interesting industrial applications where fractional-order transfer functions are used for modeling and control, see, e.g., Monje et al. (2010); typically, such functions are rational in s^α, where α is a rational number in the open interval $(0, 1)$. Transfer functions of systems with time delays involve terms like e^{-hs} where $h > 0$ is the delay; see Sipahi et al. (2011) for

various real-life examples where time-delay models appear. Transfer functions considered here are functions of the complex variable s with real coefficients, so $\overline{P(\bar{s})} = P(s)$ where $\bar{s}$ denotes the complex conjugate of s.

Definition 2 A linear time invariant system H is said to be *stable* if its transfer function $H(s)$ is bounded and analytic in $\mathbb{C}_+$. In this case, the *system norm* is

$$\|H\| = \|H\|_\infty = \sup_{\mathrm{Re}(s)>0} |H(s)|,$$

which is equivalent to the *energy amplification* through the system H; see Doyle et al. (1992) and Foias et al. (1996).

Definition 2 is sometimes called the $\mathcal{H}_\infty$-stability, and in this setting, the set of all stable plants is the function space $\mathcal{H}_\infty$. It is worth noting that for infinite-dimensional systems, there are other definitions of stability (Curtain and Zwart 1995; Desoer and Vidyasagar 2009), leading to different measures of the system norm.

Robust Control Design Objectives

Let $\mathcal{F}(C, P_\Delta)$ denote the feedback system shown in Fig. 1. This system is said to be *robustly stable* if all the transfer functions from external inputs (r, v) to internal signals (e, u) are in $\mathcal{H}_\infty$ for all $P_\Delta \in \mathcal{P}$. In the controller design, robust stability of the feedback system is the primary constraint.

The feedback system $\mathcal{F}(C, P_\Delta)$ is robustly stable if and only if the following conditions hold; see, e.g., Doyle et al. (1992) and Foias et al. (1996),

(a) $S, CS, PS \in \mathcal{H}_\infty$, where $S = (1 + PC)^{-1}$, and

(b) $\|W\,CS\|_\infty \le 1$.

In order to illustrate these design constraints for robustly stabilizing controller, as an example, consider a strictly proper stable plant, i.e.,

$$P \in \mathcal{H}_\infty \quad \text{with} \quad \lim_{|s|\to\infty} |P(s)| = 0.$$

In this case, all controllers in the form $C = Q/(1 - PQ)$ satisfy condition (a) for any $Q \in \mathcal{H}_\infty$ (moreover, any controller C satisfying (a) must be in this form for some $Q \in \mathcal{H}_\infty$). Now consider a rational $W(s)$ with a stable Q such that $|Q(j\omega)|$ is a continuous function of $\omega \in \mathbb{R}$. Then, condition (b) becomes

$$\|WQ\|_\infty \leq 1 \iff |Q(j\omega)| \leq |W(j\omega)|^{-1}$$
$$\forall \omega \in \mathbb{R}.$$

So, whenever the modeling uncertainty is "large" on a frequency band $\omega \in \Omega$, the magnitude of Q should be "small" in this region.

When the plant is unstable, say $p \in \mathbb{C}_+$ is a pole of $P(s)$ of multiplicity one, conditions (a) and (b) impose a restriction on the controller, that leads to

$$1 \geq \|\mathrm{WCS}\|_\infty \geq \left| \frac{W(p)}{N(p)} \right| \quad \text{where} \ N(p)$$
$$= \lim_{s \to p} \frac{(s - p)}{(s + \overline{p})} \ P(s).$$

So, a necessary condition, for (b) to hold in this case, is $|W(p)| \leq |N(p)|$, which means that the modeling uncertainty at the unstable pole of the plant should be small enough for the existence of a robustly stabilizing controller. This is one of the fundamental quantifiable limitations of feedback systems with unstable plants; see Stein (2003) for further discussions on other limitations.

Many other performance-related design objectives, such as reference tracking and disturbance attenuation, are captured by the *sensitivity minimization*, which is defined as finding a controller satisfying (a) and achieving

(c) $\|W_1 S\|_\infty \leq \gamma$

for the smallest possible $\gamma > 0$, for a given stable sensitivity weight $W_1(s)$. Selection of W_1 depends on the class of reference signals and disturbances considered; see Doyle et al. (1992), Özbay (2000), and Stein (2003) for general guidelines. Stability robustness and performance objectives defined above can be blended to define a single

$\mathcal{H}_\infty$-optimization problem, known as the *mixed sensitivity minimization*: given W_1, W_2, P, find a controller C satisfying (a) and achieving

(d) $\left\| \begin{bmatrix} W_1 S \\ W_2 T \end{bmatrix} \right\|_\infty :=$

$$\sup_{\mathrm{Re}(s) > 0} \left(|W_1(s)S(s)|^2 + |W_2(s)T(s)|^2 \right)^{\frac{1}{2}} \leq \gamma$$

for the smallest possible $\gamma > 0$, where $T(s) := 1 - S(s)$ and $W_2(s)$ represents the multiplicative uncertainty bound, with $|W_2(j\omega)| = |W(j\omega)|/|P(j\omega)|$, $\forall \ \omega \in \mathbb{R}$. The smallest achievable γ is the optimal performance level γ_{opt} and the corresponding controller is denoted by C_{opt}. Typically, when P is infinite dimensional so is the optimal controller.

Design Methods

Approximation of the Plant
One possible way to design a robust controller for an infinite-dimensional plant P is to design a robust controller C_a for an approximate finite-dimensional plant P_a; (for a frequency domain approximation technique for infinite-dimensional systems, see Gu et al. 1989). When W_1, W_2, and P_a are finite dimensional, standard state-space methods, Zhou et al. (1996), can be used to find an $\mathcal{H}_\infty$ controller C_a achieving

$$\left\| \begin{bmatrix} W_1 S_a \\ W_2 T_a \end{bmatrix} \right\|_\infty \leq \gamma_a$$

for the smallest possible γ_a, where $S_a := (1 + P_a C_a)^{-1}$ and $T_a = (1 - S_a)$. Then, the controller $C = C_a$ satisfies (a) and achieves the performance objective (d) with

$$\gamma = (\gamma_a + \varepsilon) \ \frac{1}{1 - \varepsilon}, \quad \varepsilon := \|C_a S_a (P - P_a)\|_\infty,$$

where it is assumed that the approximation of the plant is made in such a way that $\varepsilon < 1$. Clearly, if $\gamma_a \to \gamma_{\mathrm{opt}}$ as $\varepsilon \to 0$, then $\gamma \to \gamma_{\mathrm{opt}}$ as

R

$\varepsilon \to 0$. The conditions under which $\gamma_a \to \gamma_{\mathrm{opt}}$ are discussed in Morris (2001).

Direct Design Methods

The classical two-Riccati equation approach, Zhou et al. (1996), developed for finite-dimensional systems, has been extended to various classes of infinite-dimensional systems by using the state-space techniques where semigroup theory plays an important role; see van Keulen (1993) for further details.

In order to illustrate some of the key steps of a frequency domain method developed in Foias et al. (1996), consider a specific example where the plant is given as

$$P(s) = \frac{(s-1)(s+2)\,e^{-hs}}{(s^2+2s+2)(s+1-3e^{-2hs})} \, ,$$
$$h = \ln(2) \approx 0.693. \qquad (1)$$

First, compute the location of the poles in $\mathbb{C}_+$ using available numerical tools for finding the roots of quasi-polynomials; see, e.g., Sipahi et al. (2011) for references. For the simple example chosen here, $P(s)$ has only one pole in $\mathbb{C}_+$, at $s = 0.5$ (for larger values of h, the number of unstable poles of P may be higher). Now, the plant can be factored as follows:

$$P(s) = \frac{M_N(s)N_O(s)}{M_D(s)} \qquad (2)$$

where

$$M_N(s) = \frac{s-1}{s+1}\,e^{-hs} \qquad M_D(s) = \frac{s-0.5}{s+0.5}$$

are all-pass (inner) transfer functions and

$$N_O(s) = \frac{(s+2)(s+1)}{(s^2+2s+2)(s+0.5)}$$
$$\left(\frac{s-0.5}{s+1-3e^{-2hs}} \right)$$

is a minimum-phase (outer) transfer function. Note that

$$\frac{s-0.5}{s+1-3e^{-2hs}} = \frac{1}{1+H_F(s)} \, ,$$
$$H_F(s) = 1.5\,\frac{1-e^{-2h(s-0.5)}}{s-0.5}. \qquad (3)$$

The impulse response of H_F is $h_F(t) = 1.5e^{t/2}$ when $t \in [0, 2h]$ and $h_F(t) = 0$ otherwise. Stability of N_O can also be verified from the Nyquist graph of H_F. Also, note that $N_O(s)$ can be factored as $N_O(s) = N_1(s)N_2(s)$ where

$$N_1(s) = \frac{(s+2)(s+1)}{(s^2+2s^2+2)} \left(\frac{1}{1+H_F(s)} \right),$$
$$N_2(s) = \frac{1}{s+0.5}$$

with $N_1, N_1^{-1} \in \mathcal{H}_\infty$ and N_2 is finite-dimensional (first order in this example).

The above steps illustrate *coprime factorizations* and *inner-outer factorizations* for systems with time delays (retarded case). For systems represented by PDEs or integrodifferential equations, plant transfer function can be factored similarly, provided that the poles and zeros in $\mathbb{C}_+$ can be computed numerically.

When the plant is in the form (2) given above and the weights W_1 and W_2 are rational, the optimal performance level and the corresponding optimal controller is obtained by the following procedure (see Foias et al. (1996) for details).

- *Controller parameterization* transforms the mixed sensitivity minimization to a problem of finding the smallest $\gamma > 0$ for which there exists $Q \in \mathcal{H}_\infty$ such that

$$\left\| \begin{bmatrix} W_1 \\ 0 \end{bmatrix} - \begin{bmatrix} W_1 N_2 \\ -W_2 N_2 \end{bmatrix} M_N(R + M_D Q) \right\|_\infty \le \gamma$$

where $R(s)$ is a rational function (whose order is one less than the order of M_D) satisfying certain interpolation conditions at the zeros of $M_D(s)$.

- A *spectral factorization* determines $W_0 \in \mathcal{H}_\infty$ such that $W_0^{-1} \in \mathcal{H}_\infty$ and

$$\left(|W_1(j\omega)|^2 + |W_2(j\omega)|^2 \right) |N_2(j\omega)|^2$$
$$= |W_0(j\omega)|^2 \quad \forall \, \omega \in \mathbb{R},$$

(here, it is assumed that $W_2 N_2$ and $(W_2 N_2)^{-1}$ are in $\mathcal{H}_\infty$).

- By using the norm preserving property of the unitary matrices and the *commutant lifting theorem*, it has been shown that

$$\gamma_{\mathrm{opt}} = \left\| \begin{bmatrix} \Gamma \\ \Upsilon \end{bmatrix} \right\|$$

where Γ is the *Hankel operator* whose symbol is

$$M_D(-s)\left(M_N(-s) W_0^{-1}(-s) N_2(-s) W_1(-s) W_1(s) - W_0(s) R(s) \right)$$

and Υ is the *Toeplitz operator* whose symbol is $W_1(s) W_2(s) N_2(s) W_0^{-1}(s)$. Moreover, under mild technical assumptions, the optimal controller is obtained from a nonzero $\psi_o \in \mathcal{H}_2$ satisfying

$$\left(\gamma_{\mathrm{opt}}^2 - (\Gamma^* \Gamma + \Upsilon^* \Upsilon) \right) \psi_o = 0$$

The operator $(\Gamma^* \Gamma + \Upsilon^* \Upsilon)$ is in the form of a *skew-Toeplitz operator* that gives the name to this approach. See Foias et al. (1996) for a detailed exposition.

Optimal $\mathcal{H}_\infty$-Controller

The above steps have been implemented, and the final optimal controller expression has been obtained in a simplified form described below.

Let $\alpha_1, \ldots, \alpha_\ell \in \mathbb{C}_+$ be the zeros of $M_D(s)$, i.e., unstable poles of the plant (for simplicity of the exposition, they are assumed to be distinct). The sensitivity weight can be written as $W_1(s) = n W_1(s)/d W_1(s)$, for two coprime polynomials $n W_1$ and $d W_1$ with $\deg(n W_1) \le \deg(d W_1) =: n_1 \ge 1$. Define

$$E_\gamma(s) := \left(\frac{W_1(-s) W_1(s)}{\gamma^2} - 1 \right)$$

and let $\beta_1, \ldots, \beta_{2n_1}$ be the zeros of $E_\gamma(s)$, enumerated in such a way that $-\beta_{n_1+k} = \beta_k \in \overline{\mathbb{C}}_+$, for $k = 1, \ldots, n_1$. For notational convenience, assume that the zeros of E_γ are distinct for $\gamma = \gamma_{\mathrm{opt}}$.

Now define a rational function depending on $\gamma > 0$ and the weights W_1 and W_2,

$$F_\gamma(s) := \gamma \frac{d W_1(-s)}{n W_1(s)} G_\gamma(s)$$

where $G_\gamma \in \mathcal{H}_\infty$ is an outer function determined from the spectral factorization

$$G_\gamma(-s) G_\gamma(s)$$
$$= \left(1 + \frac{W_2(-s) W_2(s)}{W_1(-s) W_1(s)} - \frac{W_2(-s) W_2(s)}{\gamma^2} \right)^{-1}.$$

With the above definitions, under certain mild conditions (satisfied generically in most practical cases), the optimal controller can be expressed as

$$C_{\mathrm{opt}}(s) = \frac{E_\gamma(s) M_D(s) F_\gamma(s) L(s)}{1 + M_N(s) F_\gamma(s) L(s)} N_O^{-1}(s) \quad (4)$$

where $\gamma = \gamma_{\mathrm{opt}}$ and $L(s) = L_2(s)/L_1(s)$ with polynomials L_1 and L_2, of degree $n_1 + \ell - 1$, determined from the interpolation conditions:

$$L_1(\beta_k) + M_N(\beta_k) F_\gamma(\beta_k) L_2(\beta_k) = 0 \qquad k = 1, \ldots, n_1$$
$$L_1(\alpha_k) + M_N(\alpha_k) F_\gamma(\alpha_k) L_2(\alpha_k) = 0 \qquad k = 1, \ldots, \ell$$
$$L_2(-\beta_k) + M_N(\beta_k) F_\gamma(\beta_k) L_1(-\beta_k) = 0 \qquad k = 1, \ldots, n_1$$
$$L_2(-\alpha_k) + M_N(\alpha_k) F_\gamma(\alpha_k) L_1(-\alpha_k) = 0 \qquad k = 1, \ldots, \ell.$$

The above system of equations can be rewritten in the matrix form

$$\mathcal{R}_\gamma\, \Phi = 0 \tag{5}$$

where the $2(n_1 + \ell) \times 1$ vector Φ contains the coefficients of L_1 and L_2, and $\mathcal{R}_\gamma$ is a $2(n_1 + \ell) \times 2(n_1 + \ell)$ matrix which can be computed numerically when γ is fixed. The optimal performance level γ_{opt} is the largest γ which makes $\mathcal{R}_\gamma$ singular. The corresponding nonzero Φ gives $L(s)$, and hence, all the components of C_{opt} are computed.

Example 1 Consider the weighted sensitivity minimization for the plant (1) with the following first-order weights:

$$W_1(s) = \frac{1}{s}, \quad W_2(s) = k\, s \tag{6}$$

where $k > 0$ represents the relative importance of the multiplicative uncertainty with respect to the tracking performance under steplike reference inputs (see Doyle et al. 1992; Özbay 2000). With (6) the functions $E_\gamma(s)$ and $F_\gamma(s)$ are computed as

$$E_\gamma(s) = \frac{1 + \gamma^2 s^2}{-\gamma^2 s^2}, \quad F_\gamma(s) = \frac{-\gamma\, s}{k s^2 + k_\gamma s + 1},$$

where $\quad k_\gamma = \sqrt{2k - \dfrac{k^2}{\gamma^2}}. \tag{7}$

In this example $\ell = 1$ and $n_1 = 1$, with $\alpha_1 = 0.5$, $\beta_1 = j/\gamma$. For $k = 0.1$, the largest γ which makes $\mathcal{R}_\gamma$ singular is $\gamma_{\mathrm{opt}} = 7.452$, and the coefficients of the corresponding $L(s)$ are computed from the SVD of $\mathcal{R}_{\gamma_{\mathrm{opt}}}$,

$$L(s) = \frac{-0.0867 - 0.99623\, s}{-0.0867 + 0.99623\, s} = \frac{0.087 + s}{0.087 - s}.$$

Note that zeros of $E_\gamma(s) M_D(s)$ in $\overline{\mathbb{C}}_+$ appear as roots of the equation

$$1 + M_N(s) F_\gamma(s) L(s) = 0.$$

Hence, there are *internal* unstable pole-zero cancelations in the representation (4). An internally stable implementation of this controller is shown in Gumussoy (2011) using a realization similar to (3).

The above approach can also be extended to a class of infinite-dimensional plants with infinitely many poles in $\mathbb{C}_+$; see Gumussoy and Özbay (2004) for technical details.

Summary and Future Directions

This entry briefly summarized robust control problems involving linear time invariant infinite-dimensional plants with dynamic uncertainty models. Salient features of these robust control problems are captured by the mixed sensitivity minimization problem, for which a numerical computational procedure is outlined under the assumption that the weights are rational functions. Note that different types of plant models involving probabilistic, parametric, or structured (MIMO case) uncertainty are left out in this entry. Other robust control problems that are not discussed here include simultaneous stabilization (control of finitely many plant models by a single robust controller) and strong stabilization (robust control with the added restriction that the controller must be stable) of infinite-dimensional systems. Stable robust controller design techniques for different types of systems with time delays are illustrated in Özbay (2010) and Wakaiki et al. (2013); see also their references.

For practical implementation of infinite-dimensional robust controllers, it is important to find low-order approximations of stable irrational transfer functions with prescribed $\mathcal{H}_\infty$ error bound. There exist many different approximation techniques for various types of transfer functions, but there is still need for computationally efficient algorithms in this area. Another interesting topic along the same lines is direct computation of fixed-order $\mathcal{H}_\infty$ controllers for infinite-dimensional plants. In fact, computation of $\mathcal{H}_\infty$-optimal PID controllers is still a challenging

problem for infinite-dimensional plants, except for some time-delay systems satisfying certain simplifying structural assumptions. Advances in numerical optimization tools will play critical roles in the computation of low (or fixed)-order robust controller design for infinite-dimensional plants; see, e.g., Gumussoy and Michiels (2011) for recent results along this direction.

In the past, robust control of infinite-dimensional systems found applications in many different areas such as chemical processes, flexible structures, robotic systems, transportation systems, and aerospace. Robust control problems involving systems with time-varying and uncertain time delays appear in control of networks and control over networks. Ongoing research in the networked systems area include generalization of these problems to more complex and interconnected systems.

There are also many interesting robust control problems in biological systems, where typical underlying plant models are nonlinear and infinite dimensional. Some of these problems are solved under simplifying assumptions; it is expected that robust control theory will make significant contributions to this field by extensions of the existing results to more realistic plant and uncertainty models.

Robust Fault Diagnosis and Control

Steven X. Ding
University of Duisburg-Essen, Duisburg, Germany

Abstract

Aiming at increasing system reliability and availability, integration of fault diagnosis into feedback control systems and integrated design of control and diagnosis receive considerable attention in research and industrial applications. In the framework of robust control, integrated diagnosis and control systems are designed to meet the demand for system robustness. The core of such systems is an observer that delivers needed information for a robust fault detection and feedback control.

Keywords

Observer-based fault diagnosis and control; Residual generation

Introduction

Advanced automatic control systems are marked by the high integration degree of digital electronics, intelligent sensors, and actuators. In parallel to this development, a new trend of integrating model-based fault detection and isolation (FDI) into the control systems can be observed (Blanke et al. 2006; Ding 2013; Gertler 1998; Isermann 2006; Patton et al. 2000), which is strongly driven by the enhanced needs for system reliability and availability.

A critical issue surrounding the integration of a diagnostic module into a feedback control loop is the interaction between the control and

diagnosis. Initiated by Nett et al. (1988), study on the integrated design of control and diagnosis has received much attention, both in the research and application domains. The original idea of the integrated design scheme proposed by Nett et al. (1988) is to manage the interactions between the control and diagnosis in an integrated manner (Ding 2009; Jacobson and Nett 1991).

Robustness is an essential performance for model-based control and diagnostic systems. In the control and diagnosis framework, robustness is often addressed in different context (Ding 2013) and thus calls for special attention in the integrated design of control and diagnostic systems. In their study on fault-tolerant controller architecture, Zhou and Ren (2001) have proposed to deal with the integrated design in the framework of the Youla parametrization of stabilization controllers (Zhou et al. 1996), which also builds the basis for achieving high robustness in an integrated control and diagnosis system. Below, we present the basic ideas and some representative schemes and methods for the integrated design of robust diagnosis and control systems.

Plant Model and Factorization Technique

Consider linear time invariant (LTI) systems given in the state space representation

$$\dot{x}(t) = Ax(t) + Bu(t) + E_d d(t) + E_f f(t)$$
$$y(t) = Cx(t) + Du(t) + F_d d(t) + F_f f(t)$$
$$z(t) = C_z x(t) + D_z u(t)$$

where $x \in \mathcal{R}^n, y \in \mathcal{R}^m, u \in \mathcal{R}^{k_u}$ stand for the plant state, output, and input vectors, respectively. $z \in \mathcal{R}^{k_z}$ is the controlled output vector. $d \in \mathcal{R}^{k_d}, f \in \mathcal{R}^{k_f}$ denote disturbance and fault vectors, respectively. $A, B, C, D, C_z, D_z, E_d, E_f, F_d, F_f$ are known matrices of appropriate dimensions.

A transfer matrix $G(s) = D + C(sI - A)^{-1}B$ with the minimal state space realization (A, B, C, D) can be factorized into

$$G(s) = \hat{M}^{-1}(s)\hat{N}(s)$$

$$\hat{M}(s) = I - C(sI - A_L)^{-1}L$$

$$\hat{N}(s) = D + C(sI - A_L)^{-1}B_L$$

$$A_L = A - LC, B_L = B - LD$$

where L is selected so that A_L is stable and can be interpreted as an observer gain matrix. This factorization is called left coprime (Zhou et al. 1996).

Parametrization of Stabilizing Controllers

Let

$$u(s) = K(s)y(s)$$

be an LTI feedback controller. By means of the well-known Youla parametrization (Zhou et al. 1996), all stabilizing controllers can be described and parametrized by

$$K(s) = \left(\hat{X}(s) - Q_c(s)\hat{N}(s)\right)^{-1} \cdot$$
$$\left(\hat{Y}(s) - Q_c(s)\hat{M}(s)\right)$$

$$\hat{X}(s) = I - F(sI - A_L)^{-1}B_L$$

$$\hat{Y}(s) = F(sI - A_L)^{-1}L$$

where $Q_c(s)$ is a stable parameter matrix, and F is selected so that $A_F = A + BF$ is stable and can be interpreted as a state feedback gain matrix.

Parametrizations of Residual Generators

Given the system under consideration, an LTI residual generator is a dynamic system with $u(t), y(t)$ as its inputs and $r(t)$ as output which satisfies, for $d(t) = 0, f(t) = 0$,

$$\forall x(0), u(t), \lim_{t \to \infty} r(t) = 0.$$

Residual generation is the first step for a successful fault diagnosis. The generated residual vector is an indicator for the occurrence of a fault. It is well known that all LTI residual generators can be parametrized by

$$r(s) = R(s)\left(\hat{M}(s)y(s) - \hat{N}(s)u(s)\right)$$

where $R(s)$ is a stable parameter matrix and called post-filter (Ding 2013).

Integration of Controller and Residual Generator into a Control Loop

It is remarkable that both the feedback controllers and residual generators can be parametrized based on the left coprime factorization of the plant model. This is the basis for an integration of diagnosis and control into a feedback control system. In Ding et al. (2010), it is demonstrated that the abovementioned Youla parametrization form is in fact an observer-based feedback controller, which can be expressed by

$$u(s) = F\hat{x}(s) + Q_c(s)\left(\hat{N}(s)u(s) - \hat{M}(s)y(s)\right)$$

where $\hat{x}(s)$ is a state estimate delivered by a full-order state observer (Anderson 1998; Zhou et al. 1996). Moreover, the residual generator can also be written as

$$r(s) = R(s)r_o(s), r_o(s) = y(s) - \hat{y}(s)$$

with $\hat{y}(s)$ being the output estimate delivered by an observer (Ding 2013). As a result, a stabilization feedback controller and residual generator can be integrated into a dynamic system of the following form:

$$\dot{\hat{x}}(t) = A\hat{x}(t) + Bu(t) + Lr_o(t)$$
$$= A_L\hat{x}(t) + B_Lu(t) + Ly(t)$$

$$r_o(t) = y(t) - \hat{y}(t), \hat{y}(t) = C\hat{x}(t) + Du(t)$$

$$\begin{bmatrix} u(s) \\ r(s) \end{bmatrix} = \begin{bmatrix} F\hat{x}(s) \\ 0 \end{bmatrix} + \begin{bmatrix} -Q_c(s) \\ R(s) \end{bmatrix} r_o(s).$$

The core of the above control and diagnostic system is a state observer that delivers a state estimation $\hat{x}(t)$ and the primary residual vector $r_o(t)$. The design parameters of this integrated control and diagnosis system are L, F; the observer and state feedback control gain matrices, as well as $Q_c(s), R(s)$.

Robustness of Diagnostic and Control Systems

While in the robust control framework, the controller design is typically formulated as minimizing a system norm of the transfer function matrix from the disturbance vector d to the control output z (Zhou et al. 1996), the design objective of a robust fault detection system consists in an optimal trade-off between the robustness against d and the sensitivity to the fault vector f. Considering that

$$r(s) = R(s)\,(y(s) - \hat{y}(s))$$

$$= R(s)\left(\hat{N}_d(s)d(s) + \hat{N}_f(s)f(s)\right)$$

$$\hat{N}_d(s) = F_d + C\,(sI - A_L)^{-1}\,(E_d - LF_d)$$

$$\hat{N}_f(s) = F_f + C\,(sI - A_L)^{-1}\,(E_f - LF_f)$$

Ding (2013), the design objective can be formulated as

$$\sup_{R(s)} \frac{\left\| R(s)\hat{N}_f(s) \right\|_{\text{index}}}{\left\| R(s)\hat{N}_d(s) \right\|}$$

or in a suboptimum form as finding $R(s)$ so that for some given $\alpha > 0, \beta > 0$

$$\left\| R(s)\hat{N}_d(s) \right\| \le \alpha, \left\| R(s)\hat{N}_f(s) \right\|_{\text{index}} > \beta.$$

Similar to the robust controller design, a (system) norm like $\mathcal{H}_2$ or $\mathcal{H}_\infty$ norm, denoted by $\|\cdot\|$, is applied for the evaluation of the influence of the disturbances. Differently, the evaluation of the sensitivity to the fault vector, expressed by $R(s)\hat{N}_f(s)$, can be realized using either a system norm or the so-called $\mathcal{H}_-$ index, denoted by $\|\cdot\|_-$, which indicates the minimum influence of f on r (Ding 2013).

In order to detect the fault occurrence reliably and successfully, a decision-making procedure is needed. It consists of a further evaluation of the residual signal and a detection logic. Typically, a signal norm of r, e.g., $\mathcal{L}_2$ norm, and a simple detection logic like

$$\begin{cases} \|r\| > J_{th} \Longrightarrow \text{Alarm for fault} \\ \|r\| \le J_{th} \Longrightarrow \text{Fault-free} \end{cases}$$

are adopted for this purpose, where J_{th} is a further design parameter and called threshold (Ding 2013). The threshold setting depends on the dynamics of r, its norm-based evaluation, and has significant influence on the fault detection performance. For the purpose of reducing false alarms, the threshold is often set as

$$J_{th} = \sup_{f=0, \|d\| \le d_d} \|r\|$$

$$= \sup_{f=0, \|d\| \le d_d} \left\| R(s)\hat{N}_d(s)d(s) \right\|.$$

That is, the threshold is set to be the maximum value of the influence of the disturbances on the residual signal in the fault-free case. Thus, different designs of the residual generator will result in different threshold settings. In this context, an optimal design of a fault diagnosis system is understood as an integrated design of the residual generator, the evaluation function, and the threshold (Ding 2013).

An Integrated Design Scheme for Robust Diagnosis and Control

Assume that the system under our consideration satisfies the following conditions:

- $\|d\|_2 \le \delta_d$.
- (A, B) is stabilizable and (C, A) is detectable.
- $D = 0$.
- $D_z^T D_z > 0$ and $F_d F_d^T > 0$.
- $\begin{bmatrix} A - j\omega I & B \\ C_z & D \end{bmatrix}$ has full column rank for all ω.
- $\begin{bmatrix} A - j\omega I & E_d \\ C & F_d \end{bmatrix}$ has full row rank for all ω.

Then, the following observer and state feedback gain matrices

$$L^* = \left(E_d F_d^T + Y C^T\right)\left(F_d F_d^T\right)^{-1}$$
$$F^* = -\left(D_z^T D_z\right)^{-1}\left(B^T X + D_z^T C_z\right)$$

as well as

$$Q_c^*(s) = 0, \; R^*(s) = \left(F_d F_d^T\right)^{-1/2}$$

result in an optimal integrated design of the robust diagnostic and control system with

- $\mathcal{H}_2$ optimal control performance
- Maximal fault detectability and the optimal threshold setting

$$J_{th} = \sup_{f=0, \|d\| \le \delta_d} \|r\|_2 = \delta_d$$

where $Y \ge 0$, $X \ge 0$ are respectively the solution of the following two Riccati equations:

$$AY + YA^T + E_d E_d^T - \left(E_d F_d^T + Y C^T\right) \cdot$$
$$\left(F_d F_d^T\right)^{-1}\left(E_d F_d^T + Y C^T\right)^T = 0$$
$$A^T X + XA + C_z^T C_z - \left(C_z^T D_z + XB\right) \cdot$$
$$\left(D_z^T D_z\right)^{-1}\left(C_z^T D_z + XB\right)^T = 0.$$

That L^*, F^* lead to minimizing the $\mathcal{H}_2$ norm of the transfer matrix from d to z is a well-known result (Zhou et al. 1996). The optimal fault detection performance can be understood from two different viewpoints:

- Optimum in the sense of

$$\forall \omega, \quad \sup_{R(s)} \frac{\sigma_i\left(R(j\omega)\hat{N}_f(j\omega)\right)}{\left\| R(s)\hat{N}_d(s)\right\|_\infty}$$
$$= \sigma_i\left(\left(F_d F_d^T\right)^{-1/2} \hat{N}_f^*(j\omega)\right)$$

where $\sigma_i\left(R(j\omega)\hat{N}_f(j\omega)\right)$ is the i-th singular value of matrix $R(j\omega)\hat{N}_f(j\omega)$, $i = 1, \cdots, k_f$, $\hat{N}_f^*(s) = \hat{N}_f(s)|_{L=L^*}$ (Ding 2013).

- A fault that can be detected by any LTI detection system will also be detected using the detection system with the above parameter and threshold setting. Thus, this detection system provides the maximal fault detectability (Ding 2013).

It is worth remarking that:

- The assumptions mentioned above are standard in the $\mathcal{H}_2$ optimal control (Zhou et al. 1996).
- The optimization problem

$$\forall \omega, \sup_{R(s)} \frac{\sigma_i\left(R(j\omega)\hat{N}_f(j\omega)\right)}{\left\| R(s)\hat{N}_d(s)\right\|_\infty}$$

is a more general form of the so-called $\mathcal{H}_-/\mathcal{H}_\infty$ or $\mathcal{H}_\infty/\mathcal{H}_\infty$ optimization of observer-based fault detection systems, and thus, its solution is called unified solution (Ding 2013).

- The solution given above is a state space realization of the robust fault detection problems, which is e.g., described by Ding (2013) in Theorem 7.16.
- This integrated design scheme can also be applied to discrete-time and stochastic systems (Ding 2013).

Summary and Future Directions

Increasing reliability and availability of advanced automatic control systems is of considerable practical interests. Integration of fault diagnosis into feedback control systems and integrated design of robust control and diagnosis are useful solutions for real-time applications (Ding 2009). They can also be integrated into a fault-tolerant control system (Blanke et al. 2006; Zhou and Ren 2001). A further potential application field is fault diagnosis in feedback control loops using embedded residual signals (Ding et al. 2010).

From the viewpoint of research, integrated design of robust control and diagnosis in nonlinear and time-varying dynamic systems

are challenging issues. The $\mathcal{L}_2$-gain technique for nonlinear control (Van der Schaft 2000) and the fault detection scheme proposed by Li and Zhou (2009) are promising and useful results for the future investigations in this area.

Robust $\mathcal{H}_2$ Performance in Feedback Control

Fernando Paganini
Universidad ORT Uruguay, Montevideo, Uruguay

Abstract

This entry discusses an important compromise in feedback design: reconciling the superior performance characteristics of the $\mathcal{H}_2$ optimization criterion, with robustness requirements expressed through induced norms such as $\mathcal{H}_\infty$. The fact that both criteria have frequency-domain characterizations and involve similar state-space machinery motivated many researchers to seek an adequate combination. We review here robust $\mathcal{H}_2$ analysis methods based on convex optimization developed in the 1990s and comment on their implications for controller synthesis.

Keywords

Linear matrix inequalities; Mixed $\mathcal{H}_2/\mathcal{H}_\infty$ control; Robustness analysis; Structured uncertainty

Introduction

Can mathematics help us deal with the inevitable theory-practice gap? Should we be optimistic and assume that discrepancies between models and nature are random and neutral towards our actions or be pessimistic and design for the worst such discrepancies? Feedback control theory has struggled with these questions, perhaps more so than other fields.

During the surge of optimal control in the 1960s, optimism carried the day. A prominent example is the LQG ($\mathcal{H}_2$) regulator, which minimizes the effect of random disturbances and has an elegant state-space solution; in comparison, the frequency-domain designs of classical control appeared primitive and conservative. But the

pessimists struck back in the late 1970s, showing things could go very wrong (unstable) with LQG, when a parameter variation was introduced in the plant model. This ushered in the robust control era of the 1980s, with its worst-case analysis of stability over deterministic sets of plants, leading to other design metrics such as $\mathcal{H}_\infty$ control. In this mentality, exogenous disturbances were also treated as an adversary to be protected against in the worst case, perhaps an excess of pessimism.

The robust $\mathcal{H}_2$ problem incarnates the search for a middle ground, where stability is treated with the conservatism it deserves, but performance is optimized for a more neutral noise. This entry summarizes efforts made around the 1990s to seek this compromise.
$\mathcal{H}_2$ Optimal Control

In the feedback diagram of Fig. 1, signals are vector valued, and we focus on continuous time. G is a linear system with a given state-space representation. Initially omit the upper loop (set $\Delta = 0$). The LQG regulator is the controller K that internally stabilizes the feedback loop and minimizes the variance of the error variable z, assuming the input v is white Gaussian noise.

For an alternative description, denote by $\hat{T}_{zv}(s)$ the closed-loop transfer function from v to z; we wish to design K such that $\hat{T}_{zv}(s)$ is analytic in $Re(s) \geq 0$ and has minimum $\mathcal{H}_2$ norm, defined by

$$\|\hat{T}_{zv}\|_{\mathcal{H}_2} = \left(\int_{-\infty}^{\infty} \mathbf{Tr}(\hat{T}_{zv}(j\omega)^* \hat{T}_{zv}(j\omega)) \frac{d\omega}{2\pi} \right)^{\frac{1}{2}};$$
$$(1)$$

here **Tr** denotes matrix trace and * denotes conjugate transpose. The equivalence between this $\mathcal{H}_2$-optimal control and LQG follows from classical filtering, modeling v as uncorrelated components of unit power spectral density over all frequency. By adding a filter in the input of G, noise of known, colored spectrum can be accommodated as well.

A different motivation, in the case of scalar v, is to observe that $\|\hat{T}_{zv}\|_{\mathcal{H}_2}^2$ is the energy ($\mathcal{L}_2$-norm square) of the system impulse response.

Robust $\mathcal{H}_2$ Performance in Feedback Control, Fig. 1
Feedback control and model uncertainty

Thus it measures the transient error in response to known inputs or initial conditions which may be generated by an impulse.

The $\mathcal{H}_2$ (LQG) optimal feedback has an elegant solution, computable in state-space through two algebraic Riccati equations (AREs). Its quick popularity was, however, hampered due to its lack of *stability margins*: a small error in model parameters can make the closed-loop unstable (Doyle 1978). This motivated methods to explicitly address such modeling errors.

Model Uncertainty and Robustness

Suppose some parameter in the model of G is uncertain, $\alpha = \alpha_0 + \kappa\delta$, $\delta \in [-1, 1]$; often, the normalized variation δ can be "pulled out" into the *uncertainty block* Δ of Fig. 1. The same technique can account for unmodeled linear time-invariant (LTI) dynamics, e.g., high frequency effects: they can be "covered" by a normalized transfer function $\hat{\Delta}(j\omega)$ and frequency weights that connect it to G. Even further, a nonlinear or time-varying (NL,TV) modeling error can be represented through an *operator* Δ in signal space. The references contain details on this modeling technique.

To analyze the effect of such errors, suppose K has been chosen to stabilize G and M is the resulting closed-loop system, with state-space representation

$$\dot{x} = Ax + B_p p + B_v v, \qquad (2)$$
Robust $\mathcal{H}_2$ Performance in Feedback Control, Fig. 2
Robustness analysis setup

$$q = C_q x,$$
$$z = C_z x.$$

A is an $n \times n$ stable (Hurwitz) matrix, and for simplicity there are no feed-through terms. Figure 2, represents the interconnection of M with the uncertainty.

To quantify the size of uncertainty, it is convenient to use an *induced norm* (gain) in signal space and constrain Δ to the normalized ball $\{\|\Delta\| \leq 1\}$. If the subsystem M_{qp} in feedback with Δ satisfies itself the induced norm constraint $\|M_{qp}\| < 1$, the small gain theorem implies *robust stability* over the entire ball. Focusing for the rest of this article on the $\mathcal{L}_2$ signal space (square-integrable functions), the latter induced norm is equivalent to the $\mathcal{H}_\infty$ norm of the transfer function:

$$\|\hat{M}_{qp}(s)\|_{\mathcal{H}_\infty} := \operatorname*{ess\,sup}_{\omega \in \mathbb{R}} \bar{\sigma}(\hat{M}_{qp}(j\omega)),$$

where $\bar{\sigma}(\cdot)$ denotes matrix maximum singular value.

This motivates $\mathcal{H}_\infty$-optimal control: design K to minimize the above quantity with internal stability. This problem also admits state-space solutions based on AREs and thus is a valid competing paradigm to $\mathcal{H}_2$.

To accommodate multiple sources of uncertainty within Fig. 1, we can use a *block diagonal* structure:

$$\Delta = \operatorname{diag}[\Delta_1, \ldots, \Delta_d]. \tag{3}$$

Here, different uncertainty blocks (parametric, LTI, LTV, or NL) enter in separate "channels"; $\mathbf{B_\Delta}$ denotes the unit ball of operators with the prescribed structure. For stability studies, *causality* of the operator is required.

Robust stability under structured uncertainty is a rich topic: we refer to the article on the *structured singular value* (μ) in this encyclopedia. We invoke here robustness conditions based on the set Λ of positive definite matrix *scalings* or *multipliers* of the form:

$$\Lambda = \operatorname{diag}[\lambda_1 I, \ldots, \lambda_d I], \tag{4}$$

with submatrices of the same dimensions as the blocks in (3), thus commuting with a matrix Δ of that structure.

Consider the frequency family of matrix inequalities

$$\hat{M}_{qp}^*(j\omega)\Lambda(\omega)\hat{M}_{qp}(j\omega) - \Lambda(\omega) < 0 \quad \forall \omega;$$
$$\Lambda(\omega) \in \Lambda. \tag{5}$$

At each ω, this is a linear matrix inequality (LMI); testing its feasibility is a convex, tractable problem. A solution implies the *scaled-small gain condition*

$$\bar{\sigma}\left(\Lambda(\omega)^{\frac{1}{2}}\hat{M}_{qp}(j\omega)\Lambda^{-\frac{1}{2}}(\omega)\right) < 1;$$

this "μ upper bound" implies robust stability when uncertainty is LTI, through commuting $\Lambda(\omega)$ with $\hat{\Delta}(j\omega)$.

If uncertainty is NLTV, (5) must be strengthened to enforce $\Lambda(\omega) \equiv \Lambda$, constant in frequency. This condition turns out to be both necessary and sufficient for robust stability. Here the LMIs would be coupled in frequency; however, the Kalman-Yakubovich-Popov lemma reduces them to an equivalent LMI in terms of the state-space matrices in (2), with variables $\Lambda \in \mathbf{\Lambda}$ and an $n \times n$ matrix $P > 0$:

$$\begin{bmatrix} A^*P + PA + C_q^*\Lambda C_q & PB_p \\ B_p^*P & -\Lambda \end{bmatrix} < 0. \tag{6}$$

What about performance? The mapping $T_{zv}(\Delta)$ between the disturbance v and the error z now depends on the uncertainty. The default procedure in robust control has been to measure performance with the same induced norm, evaluating $\|T_{zv}(\Delta)\|_{\mathcal{L}_2 \to \mathcal{L}_2}$ in the worst-case over $\Delta \in \mathbf{B_\Delta}$. This can be computed with similar complexity to establishing robust stability. It amounts, however, to treating noise with the same worst-case mentality as stability, a questionable choice. For instance, in LTI systems the worst-case signals are sinusoids at the worst frequency and spatial direction; while one should protect against such signals arising in the Δ-loop due to instability, it is not natural to expect them as external disturbances, which are usually of broad spectrum.

Robust $\mathcal{H}_2$ Performance Analysis

In the absence of uncertainty, the $\mathcal{H}_2$ norm of the nominal mapping $T_{zv}(0) = M_{zv}$ provides a natural performance criterion, measuring the response to flat-spectrum disturbances or the transient response. When uncertainty is present, it motivates a worst-case analysis of stability; a natural combination is to impose *robust $\mathcal{H}_2$ performance*: evaluating the worst-case $\mathcal{H}_2$ norm of $T_{zv}(\Delta)$ over the uncertainty class $\mathbf{B_\Delta}$. We will highlight some methods based on semidefinite programming to perform such evaluations; for further details and comparisons, we refer to Paganini and Feron (1999).

A Frequency Domain Robust Performance Criterion

Consider the following optimization:

$$\mathbf{J_f} := \inf \int_{-\infty}^{\infty} \mathbf{Tr}(Y(\omega))\frac{d\omega}{2\pi}, \text{ subject to}$$

$$\hat{M}(j\omega)^* \begin{bmatrix} \Lambda(\omega) & 0 \\ 0 & I \end{bmatrix} \hat{M}(j\omega) - \begin{bmatrix} \Lambda(\omega) & 0 \\ 0 & Y(\omega) \end{bmatrix} < 0 \tag{7}$$

for each ω, and $\Lambda(\omega) \in \Lambda$.

Here $\hat{M}$ is the transfer function in Fig. 2; a submatrix of the above includes (5), implying

robust stability under structured LTI uncertainty. Furthermore, we have the robust $\mathcal{H}_2$ performance bound (Paganini 1999):

$$\sup_{\Delta \in \mathbf{B_\Delta^{LTI}}} \|T_{zv}(\Delta)\|_{\mathcal{H}_2}^2 \le \mathbf{J_f}. \tag{8}$$

We sketch the argument based on the Fourier transforms $\hat{p}(j\omega)$, etc., for signals in Fig. 2. Applying the quadratic form in (7) to the joint vector of $\hat{p}$ and $\hat{v}$ gives

$$\sum_{i=1}^{d} \lambda_i(\omega)|\hat{q}_i|^2 + |\hat{z}|^2 \le \sum_{i=1}^{d} \lambda_i(\omega)|\hat{p}_i|^2 + \hat{v}^* Y(\omega)\hat{v}.$$

The subvectors $\hat{p}_i$, $\hat{q}_i$ correspond to uncertainty blocks, $\hat{p}_i = \hat{\Delta}_i(j\omega)\hat{q}_i$; since $\bar{\sigma}(\hat{\Delta}_i(j\omega)) \le 1$, $|\hat{q}_i| \ge |\hat{p}_i|$. Also $\lambda_i(\omega) > 0$, so these terms can be simplified, leading to

$$|\hat{T}_{zv}(j\omega)\hat{v}|^2 = |\hat{z}|^2 \le \hat{v}^* Y(\omega)\hat{v}.$$

This means $\hat{T}_{zv}(j\omega)^* \hat{T}_{zv}(j\omega) \le Y(\omega)$ for every Δ, and therefore the $\mathcal{H}_2$ norm bound

$$\|T_{zv}(\Delta)\|_{\mathcal{H}_2}^2 \le \int_{-\infty}^{\infty} \mathbf{Tr}(Y(\omega))\frac{d\omega}{2\pi}$$

holds, from which (8) follows.

The computation involved in (7) at each frequency is a semidefinite program (SDP): minimizing the linear cost $\mathbf{Tr}(Y(\omega))$ subject to an LMI constraint, a tractable problem. Adding a frequency sweep, we have a practical method to bound the desired robust performance.

The inequality (8) is in general strict. Beyond the usual conservatism of convex bounds for μ, when noise is of dimension m, a conservatism of up to this order may appear; an improvement to address this issue with augmented SDPs is given in Sznaier et al. (2002). Finally, causality of the uncertainty is not imposed in the frequency-domain criterion.

As in the study of robust stability, we wish to extend the analysis to NLTV uncertainty blocks. Now the mapping $T_{zv}(\Delta)$ can no longer be represented by a transfer function, so what is the "$\mathcal{H}_2$" cost? We return to our motivation for this

performance notion: to measure the effect of disturbances of flat spectrum.

In Paganini (1999), the flat-spectrum property is imposed as a deterministic constraint on the input disturbances. For the scalar v case, define $W_{\eta,B} \subset \mathcal{L}_2$ by the family of *integral quadratic constraints*:

$$\int_{-\beta}^{\beta} |v(j\omega)|^2 \frac{d\omega}{2\pi} \begin{cases} \leq \frac{\beta}{\pi} + \eta & \forall \beta; \\ \geq \frac{\beta}{\pi} - \eta, & \beta \in [0, B]. \end{cases} \quad (9)$$

This imposes that the cumulative spectrum is approximately linear (to a tolerance $\eta > 0$), up to bandwidth B, and has sublinear growth beyond that. Extensions to vector-valued signals are also given. For a stable LTI system T_{zv}, it is not difficult to verify that

$$\|T_{zv}\|_{\mathcal{H}_2}^2 = \lim_{\substack{\eta \to 0 \\ B \to \infty}} \sup_{v \in W_{\eta,B}} \|T_{zv} v\|_2^2,$$

but the right-hand side applies to NLTV systems as well. The following result can be established in the latter case:

$$\lim_{\substack{\eta \to 0 \\ B \to \infty}} \sup_{v \in W_{\eta,B}, \Delta \in \mathbf{B}_\Delta^{\mathbf{NLTV}}} \|T_{zv}(\Delta)v\|_2^2 = \mathbf{J}_\mathbf{f}',$$

where the right-hand side is the variant of (7) with the restriction that $\Lambda(\omega) \equiv \Lambda$, constant in frequency. In this case the characterization is *exact*, with equality above. This follows from a duality argument in function space, where $Y(\omega)$ appears as the multiplier for the constraint in (9). While coupled in frequency, $\mathbf{J}_\mathbf{f}'$ is again equivalent to a finite-dimensional SDP in state space.

Let us review, instead, a different state-space method, motivated by alternate definitions of the $\mathcal{H}_2$ cost.

A State-Space Criterion Invoking Causality

Consider the semidefinite program

$$\mathbf{J}_\mathbf{s} := \inf \, \mathbf{Tr}(B_v^* P B_v) \text{ subject to } P > 0, \Lambda \in \Lambda,$$

$$\begin{bmatrix} A^* P + PA + C_q^* \Lambda C_q + C_z^* C_z & PB_p \\ B_p^* P & -\Lambda \end{bmatrix} < 0. \quad (10)$$

The LMI above is very similar to (6); indeed it provides a robust stability certificate and in addition a bound on a generalized $\mathcal{H}_2$ cost, for arbitrary (NLTV) causal uncertainty blocks. Again, we sketch the argument.

For stability, consider the system of Fig. 2 with $v \equiv 0$, initial condition $x(0) = x_0$. Define the storage function $V(x) = x^* P x$; differentiating it under (2) and applying the LMI (10) to the joint vector of $x(t)$, $p(t)$ yield

$$\dot{V} + |z|^2 \leq -q^* \Lambda q + p^* \Lambda p = \sum_{i=1}^{d} \lambda_i (|p_i|^2 - |q_i|^2).$$

Integrating the above over $(0, t)$, the sum on the right becomes nonpositive because $\lambda_i > 0$ and the operator $\Delta_i : q_i \to p_i$ is causal and contractive. This leads to

$$V(x(t)) + \int_0^t |z(\tau)|^2 d\tau \leq V(x_0), \quad (11)$$

which implies Lyapunov stability; the bound can be sharpened to prove asymptotic stability. Also, letting $t \to \infty$ yields the energy bound $\|z\|_2^2 \leq V(x_0)$.

Suppose now that x_0 is generated by applying to the (causal) system at rest, an impulse $v(t) = \delta(t)$, assumed scalar. The result is $x(0+) = B_v$, so $V(x_0) = B_v^* P B_v$; the impulse response energy of $T_{zv}(\Delta)$ is thus bounded. Minimizing over P, Λ leads to the robust $\mathcal{H}_2$ performance bound

$$\sup_{\Delta \in \mathbf{B}_\Delta^{\mathbf{NLTV}}} \|T_{zv}(\Delta)\delta(t)\|_2^2 \leq \mathbf{J}_\mathbf{s},$$

where the $\mathcal{H}_2$ cost is generalized as the impulse response energy. An extension to multiple impulse channels is available. This kind of result was first obtained by Stoorvogel (1993) for unstructured uncertainty.

An alternate notion of $\mathcal{H}_2$ cost for NLTV systems, also considered in Stoorvogel (1993), is the average output variance when the input

is random white noise. This is formalized by replacing (2) with a stochastic differential equation (e.g., Oksendal 1985) and extending the bound (11) using Ito calculus; for details see Paganini and Feron (1999). The following robust $\mathcal{H}_2$ performance bound is obtained:

$$\limsup_{\tau \to \infty} \frac{1}{\tau} \int_0^\tau E|z(t)|^2 dt. \leq \mathbf{J_s} \quad \forall \Delta \in \mathbf{B_\Delta^{NLTV}}.$$

What if the uncertainty is time invariant? Incorporating frequency-dependent scalings, with causality, into the state-space approach must be done approximately, generating $\hat{\Lambda}(j\omega)$ through the span of a predefined finite basis of causal, rational transfer functions. Searching over this basis for a bound on the impulse response energy can be pursued with state-space SDPs, now of a size increasing with the basis dimensionality. We refer to Feron (1997) for details.

Robust $\mathcal{H}_2$ Synthesis

Prior sections have focused on the robustness *analysis* of a closed-loop system M, obtained from G after designing a nominally stabilizing controller. Can we *synthesize K* with robust $\mathcal{H}_2$ performance as an objective? We overview some contributions to this question.

Multiobjective $\mathcal{H}_2/\mathcal{H}_\infty$ Control

Let us discuss first the more modest objective of optimizing *nominal* $\mathcal{H}_2$ performance while guaranteeing robust stability. If the uncertainty block Δ in Fig. 2 is unstructured, the problem is equivalent to

Minimize $\|\hat{M}_{zv}\|_{\mathcal{H}_2}$, subject to $\|\hat{M}_{qp}\|_{\mathcal{H}_\infty} < 1$.

Using a Youla parameterization of stabilizing controllers, $\hat{M}(s)$ depends affinely on a stable parameter $\hat{Q}(s)$; this makes the optimization over $\hat{Q}$ convex. However it has been shown to give infinite-dimensional solutions that must be approximated by suitable truncations; see Sznaier et al. (2000) and references therein.

To better exploit the state-space structure common to $\mathcal{H}_2$ and $\mathcal{H}_\infty$ synthesis, Bernstein and Haddad (1989) proposed a simplification: minimize an *auxiliary cost* that upper bounds the $\mathcal{H}_2$ norm while imposing the $\mathcal{H}_\infty$ constraint, through a common storage function. This cost is optimized by controllers of the order of the plant, characterized in terms of coupled AREs; later on Khargonekar and Rotea (1991) recast this problem using convex optimization. Also Zhou et al. (1994) and Doyle et al. (1994) studied the dual (transpose) structure.

The latter version is in fact directly related to the analysis condition (10), with a fixed $\Lambda = \lambda I$. A matrix P satisfying this condition imposes the $\mathcal{H}_\infty$ norm restriction and upper bounds the nominal $\mathcal{H}_2$ cost. This idea of imposing multiple objectives through a common storage function has more general applicability: Scherer et al. (1997) showed that all such problems admit tractable synthesis based on LMIs, with solutions of the same order as the plant.

Synthesis for Robust Performance

We have seen that rather than just an upper bound on nominal performance, (10) ensures the more stringent robust $\mathcal{H}_2$ performance requirement; therefore it becomes the basis of a robust $\mathcal{H}_2$ synthesis technique. In Stoorvogel (1993) this method is laid out for unstructured uncertainty: search linearly over the scalar λ and solve the auxiliary cost synthesis problem for each λ.

What about structured uncertainty? We run here into a general difficulty of such synthesis questions, even for robust stability alone. In that case, seeking simultaneously a controller K and a scaling Λ so that conditions (5) or (6) are satisfied by the resulting M is not a computationally friendly problem. In the absence of a general solution method, iterating between an $\mathcal{H}_\infty$ design of K for fixed Λ and the analysis conditions to find Λ is commonly used for design.

Things can be no easier for robust $\mathcal{H}_2$ performance, but the iterative procedure does generalize to the conditions in (10): for fixed K, the SDP will return structured Λ's, which can then be fixed for a multiobjective synthesis step based on the "auxiliary cost" in (10) as discussed above. If constant Λ are used (designing for NLTV

uncertainty), all controllers obtained are of the order of the plant.

If uncertainty is LTI, an alternative is to carry out the analysis step in the frequency domain, finding a $\Lambda(\omega)$, $Y(\omega)$ through (7). In the corresponding situation for μ-synthesis, where only $\Lambda(\omega)$ is found, a step of fitting and spectral factorization is needed to approximate such scalings through a rational weights, which are then incorporated into $\mathcal{H}_\infty$ synthesis. A similar frequency weight in the performance channel can approximate the effect of $Y(\omega)$, thus relying on weighted $\mathcal{H}_\infty$ synthesis to pursue the $\mathcal{H}_2$ performance objective. Of course, the order of the resulting controllers is increased.

Summary and Future Directions

The tradeoff between performance and robustness is essential to feedback control. In the case of linear multivariable design, it motivated a compromise between $\mathcal{H}_2$ performance and $\mathcal{H}_\infty$-type robustness, pursued with the state-space and frequency-domain tools common to these metrics. We have highlighted robust $\mathcal{H}_2$ analysis conditions obtained in the 1990s based on semidefinite programming, which provided the greatest flexibility to integrate the aforementioned tools and different points of view (worst-case, average case) present in this problem. As in other situations, the robust synthesis question has proven more difficult: design cannot be "automated" to the degree that was once envisioned.

The passage of time makes issues that once attracted strong attention look narrow in scope, so it is not natural to indicate directions that directly follow on this work. Perhaps the best legacy that the robust $\mathcal{H}_2$ generation can take to other problems is the willingness to integrate various disciplines (dynamics, operator theory, stochastics, optimization) to face the demands of applied mathematical research.

Robust Model-Predictive Control

Saša Raković
Oxford University, Oxford, UK

Abstract

Model-predictive control (MPC) is indisputably one of the rare modern control techniques that has significantly affected control engineering practice due to its unique ability to systematically handle constraints and optimize performance. Robust MPC (RMPC) is an improved form of the nominal MPC that is intrinsically robust in the face of uncertainty. The main objective of RMPC is to devise an optimization-based control synthesis method that accounts for the intricate interactions of the uncertainty with the system, constraints, and performance criteria in a theoretically rigorous and computationally tractable way. RMPC has become an area of theoretical relevance and practical importance but still offers the fundamental challenge of reaching a meaningful compromise between the quality of structural properties and the computational complexity.

Keywords

Introduction

RMPC is an optimization-based approach to the synthesis of robust control laws for constrained control systems subject to bounded uncertainty. RMPC synthesis can be seen as an adequately defined repetitive decision-making process, in which the underlying decision-making process is a suitably formulated robust optimal control (ROC) problem. The underlying ROC problem is specified in such a way so as to ensure that all possible predictions of the controlled state and corresponding control actions sequences satisfy constraints and that the "worst-case" cost is minimized. The decision variable in the corresponding ROC problem is a control policy (i.e., a sequence of control laws) ensuring that different control actions are allowed at different predicted states, while the uncertainty takes on a role of the adversary. RMPC utilizes recursively the solution to the associated ROC problem in order to implement the feedback control law that is, in fact, equal to the first control law of an optimal control policy.

A theoretically rigorous approach to RMPC synthesis can be obtained either by employing, in a repetitive fashion, the dynamic programming solution of the corresponding ROC problem or by solving online, in a recursive manner, an infinite-dimensional optimization problem (Rawlings and Mayne 2009). In either case, the associated computational complexity renders the exact RMPC synthesis hardly ever tractable. This computational impracticability of the theoretically exact RMPC, in conjunction with the convoluted interactions of the uncertainty with the evolution of the controlled system, constraints, and control objectives, has made RMPC an extremely challenging and active research field. It has become evident that a prominent challenge is to develop a form of RMPC synthesis that adequately handles

the effects of the uncertainty and yet is computationally plausible. Contemporary research proposals aim to address the inevitable trade-off between the quality of guaranteed structural properties and the corresponding computational complexity. A categorization of the existing proposals for RMPC synthesis can be based on the treatment of the effects of the uncertainty. In this sense, two alternative approaches to RMPC synthesis appear to be dominant.

The first category of the alternative approaches is represented by the methods that utilize, when possible, inherent robustness of nominal MPC synthesis. These proposals deploy a nominal MPC, albeit designed for a suitably modified control system, constraints, and control objectives. Such approaches are computationally practicable. However, the effects of the uncertainty are taken care of in an indirect way; the robustness properties of the controlled dynamics are frequently addressed via an *a posteriori* input-to-state stability analysis, which might be unnecessarily conservative and geometrically insensitive. Equally important drawbacks of these approaches to RMPC synthesis arise due to the fact that the nominal MPC synthesis is itself an inherently fragile (nonrobust) process; in particular, the stability property of the conventional MPC might fail to be robust (Grimm et al. 2004) and, furthermore, the optimal control of constrained discrete time systems, employed for the nominal MPC synthesis, can be a fragile process itself (Raković 2009).

The second category of RMPC design methods encapsulates the approaches that take the effects of the uncertainty into account more directly. These proposals are compatible with the emerging consensus: there is a need for the deployment of the simplifying approximations of the underlying control policy and sensible prioritization and modification of control objectives so as to simultaneously enhance computational tractability and ensure *a priori* guarantees of the desirable topological properties and system-theoretic rigor. The simplifying parameterizations of the control policy are employed primarily to allow for a computationally efficient handling of the interactions of the uncertainty with the evolution of the controlled system and constraints. The control objectives are prioritized and modified when necessary, in order to ensure that the corresponding ROC problem is computationally tractable. The effectiveness of such methods depends crucially on the ability to detect a sufficiently rich parameterization of control policy and to devise a systematic way for meaningful simplification of control objectives.

In a stark contrast to a well-matured theory of the nominal MPC synthesis, a systematic assessment of, and unified exposure to, the current state of affairs in the RMPC field is a highly demanding chore. Nevertheless, it is possible to outline the main aspects of the exact RMPC synthesis and to provide an overview of the dominant simplifying approximations.

Contemporary Setting and Uncertainty Effect

The contemporary approach to the exact RMPC synthesis is now delineated in a step-by-step manner.

The system: The most common setting in RMPC synthesis considers the control systems modelled, in discrete time, by

$$x^+ = f(x, u, w), \qquad (1)$$

where $x \in \mathbb{R}^n$, $u \in \mathbb{R}^m$, $\mathrm{w} \in \mathbb{R}^p$, and $x^+ \in \mathbb{R}^n$ are, respectively, the current state, control and uncertainty, and the successor state, while $f(\cdot, \cdot, \cdot) : \mathbb{R}^n \times \mathbb{R}^m \times \mathbb{R}^p \to \mathbb{R}^n$ is the state transition map assumed to be continuous. Thus, when x_k, u_k, and w_k are the state, the control, and the uncertainty at the time instance k, then $x_{k+1} = f(x_k, u_k, w_k)$ is the state at the time instance $k + 1$.

The constraints: The system variables x, u, and w are subject to hard constraints:

$$(x, u, w) \in \mathbb{X} \times \mathbb{U} \times \mathbb{W}, \qquad (2)$$

where the constraint sets $\mathbb{X}$ and $\mathbb{U}$ represent state and control constraints, while the constraint set $\mathbb{W}$ specifies geometric bounds on the uncertainty. The constraint sets $\mathbb{X} \subset \mathbb{R}^n, \mathbb{U} \subset \mathbb{R}^m$, and $\mathbb{W} \subset \mathbb{R}^p$ are assumed to be compact.

The control policy: It is necessary to specify, in a manner that is compatible with the type and nature of the uncertainty, the information available for the RMPC synthesis. The traditional state feedback setting treats the case in which, at any time instance k, the state x_k is known when the current control u_k is determined, while the values of the current and future uncertainty (w_{k+i}) are not known but are guaranteed to take the values within the uncertainty constraint set $\mathbb{W}$ (i.e., $w_{k+i} \in \mathbb{W}$). Within this setting, the use of a control policy,

$$\Pi_{N-1} := \{\pi_0(\cdot), \pi_1(\cdot), \ldots, \pi_{N-1}(\cdot)\}, \quad (3)$$

where N is the prediction horizon and each $\pi_k(\cdot) : \mathbb{R}^n \to \mathbb{R}^m$ is a control law, is structurally permissible and desirable.

The generalized state and control predictions: Because of the uncertainty, the ordinary state and control predictions, as employed in the nominal MPC, are not suitable. Clearly, when x and $\kappa(x)$ are the current state and control, then the successor state x^+ can take any value in the possible set of successor states $\{f(x, \kappa(x), w) : w \in \mathbb{W}\}$. Consequently, it is necessary to consider suitably generalized state and control predictions. The interaction of the uncertainty with the predicted behavior of the system is captured naturally by invoking the maps $F(\cdot, \cdot)$ and $G(\cdot, \cdot)$ specified, for any subset X of $\mathbb{R}^n$ and any control function $\kappa(\cdot) : \mathbb{R}^n \to \mathbb{R}^m$, by

$$F(X, \kappa) := \{f(x, \kappa(x), w) : x \in X, w \in \mathbb{W}\} \text{ and}$$
$$G(X, \kappa) := \{\kappa(x) : x \in X\}. \quad (4)$$

Within the considered setting, the corresponding state and control predictions are, in fact, set-valued and, for each relevant k, obey the relations

$$X_{k+1} = F(X_k, \pi_k) \text{ and } U_k = G(X_k, \pi_k), \text{ with}$$
$$X_0 := \{x\}. \quad (5)$$

The set sequences $\mathbf{X}_N := \{X_0, X_1, \ldots, X_{N-1}, X_N\}$ and $\mathbf{U}_{N-1} := \{U_0, U_1, \ldots, U_{N-1}\}$ represent the possible sets of the predicted states and control actions, which are commonly known as the state and control tubes. Evidently, the state and control tubes are functions of the initial state x and a control policy Π_{N-1}. Reversely, for a given initial state x, any structurally permissible control policy Π_{N-1} results in the possible sets of the predicted states and control actions.

The robust constraint satisfaction: One of the primary objectives in RMPC synthesis is to ensure that the generalized state and control predictions satisfy state and control constraints. Because of the repetitive nature of RMPC, it would be ideal to consider the control policy and generalized state and control predictions over the infinite horizon (i.e., for $N = \infty$). Unfortunately, this is hardly ever practicable in a direct fashion. When the prediction horizon is finite, the robust constraint satisfaction reduces to the conditions that for all $k = 0, 1, \ldots, N-1$, the set inclusions

$$X_k \subseteq \mathbb{X} \text{ and } U_k \subseteq \mathbb{U} \quad (6)$$

hold true and that the possible set of states X_N at the prediction time instance N satisfies the set inclusion

$$X_N \subseteq \mathbb{X}_f, \quad (7)$$

where $\mathbb{X}_f \subseteq \mathbb{X}$ is a suitable terminal constraint set.

The terminal constraint set: In order to account for the utilization of the control policy Π_{N-1} and generalized state and control predictions over the finite horizon N and to ensure that these can be prolonged indirectly over the infinite horizon, a terminal constraint set is employed. This set is obtained by considering the uncertain dynamics

$$x^+ = f(x, \kappa_f(x), w) \quad (8)$$

controlled by a local control function $\kappa_f(\cdot)$. The design of a control law $\kappa_f(\cdot)$ is usually performed offline in an optimal manner by considering the unconstrained version of the system (1), while the terminal constraint set $\mathbb{X}_f$ accounts locally for the state and control constraints. The terminal constraint set $\mathbb{X}_f$ is assumed to be compact and robust positively invariant for the dynamics (8) and constraint sets (2). Thus, the set $\mathbb{X}_f$ and a local control function $\kappa_f(\cdot)$ satisfy

$$F\left(\mathbb{X}_f, \kappa_f\right) \subseteq \mathbb{X}_f \subseteq \mathbb{X} \text{ and } \mathbb{U}_f$$
$$:= G\left(\mathbb{X}_f, \kappa_f\right) \subseteq \mathbb{U}, \qquad (9)$$

or, equivalently, $\mathbb{X}_f \subseteq \mathbb{X}$, and for all $x \in \mathbb{X}_f$, it holds that $\kappa_f(x) \in \mathbb{U}$ and $\forall w \in \mathbb{W}$, $f(x, \kappa_f(x), w) \in \mathbb{X}_f$. The most appropriate choice for $\mathbb{X}_f$ is the maximal robust positively invariant set for the dynamics (8) and constraint sets (2).

The generalized origin: Due to the presence of the uncertainty, the stabilization of the origin might not be attainable and, thus, it might be necessary to consider the origin in a generalized sense. The most natural candidate for the generalized origin is a minimal robust positively invariant set for the dynamics (8) and constraint sets (2). This set is entirely determined by the associated state set dynamics

$$X^+ = F\left(X, \kappa_f\right), \qquad (10)$$

which are completely induced by the local dynamics (8) and the uncertainty constraint set $\mathbb{W}$. The generalized origin, namely, the minimal robust positively invariant set, is compact and well defined in the case when the local control function $\kappa_f(\cdot)$ ensures that the corresponding map $F(\cdot, \kappa_f)$ is a contraction on the space of compact subsets of $\mathbb{X}_f$ (Artstein and Raković 2008), which we assume to be the case. The generalized origin $\mathbb{X}_{\mathcal{O}}$ is the unique solution to the fixed-point set equation.

$$X = F\left(X, \kappa_f\right), \qquad (11)$$

and is an exponentially stable attractor for the state set dynamics (10) with the basin of attraction being the space of compact subsets of $\mathbb{X}_f$. Thus, the conventional (0,0) fixed-point pair ought to be replaced by the fixed-point pair of sets $(\mathbb{X}_{\mathcal{O}}, \mathbb{U}_{\mathcal{O}})$ required to satisfy

$$\mathbb{X}_{\mathcal{O}} = F\left(\mathbb{X}_{\mathcal{O}}, \kappa_f\right) \subseteq \text{interior}\left(\mathbb{X}_f\right) \text{ and}$$
$$\mathbb{U}_{\mathcal{O}} := G\left(\mathbb{X}_{\mathcal{O}}, \kappa_f\right) \subseteq \mathbb{U}_f. \qquad (12)$$

The generalized cost functions: The performance requirements are, as usual, expressed via a cost function, which is obtained by considering a stage cost function $\ell(\cdot, \cdot) : \mathbb{X} \times \mathbb{U} \to \mathbb{R}_+$ and a terminal cost function $V_f(\cdot) : \mathbb{X}_f \to \mathbb{R}_+$. The stage cost function $\ell(\cdot, \cdot)$ is continuous and, due to the uncertainty, adequately lower bounded w.r.t. to the generalized origin $\mathbb{X}_{\mathcal{O}}$. The latter condition requires that for all $x \in \mathbb{X}$ and all $u \in \mathbb{U}$, the function $\ell(\cdot, \cdot)$ satisfies

$$\alpha_1\left(\text{dist}\left(\mathbb{X}_{\mathcal{O}}, x\right)\right) \le \ell\left(x, u\right), \qquad (13)$$

where $\alpha_1(\cdot)$ is a $\mathcal{K}$-class (Kamke's) function and $\text{dist}(\mathbb{X}_{\mathcal{O}}, \cdot)$ is the distance function from the set $\mathbb{X}_{\mathcal{O}}$. The consideration of the generalized origin requires the additional condition that for all $x \in \mathbb{X}_{\mathcal{O}}$, the use of local control function $\kappa_f(\cdot)$ is "free of charge" w.r.t. $\ell(\cdot, \cdot)$, i.e., that for all $x \in \mathbb{X}_{\mathcal{O}}$, we have

$$\ell\left(x, \kappa_f\left(x\right)\right) = 0. \qquad (14)$$

As in the case of the terminal constraint set $\mathbb{X}_f$, the terminal cost function $V_f(\cdot)$ is employed to account for the utilization of the finite prediction horizon N, and it should provide locally a theoretically suitable upper bound of the highly desired infinite horizon cost. The terminal cost function $V_f(\cdot)$ is assumed to be continuous and adequately upper bounded w.r.t. the generalized origin $\mathbb{X}_{\mathcal{O}}$. The latter bound reduces to the requirement that for all $x \in \mathbb{X}_f$, we have

$$V_f(x) \le \alpha_2\left(\text{dist}\left(\mathbb{X}_{\mathcal{O}}, x\right)\right), \qquad (15)$$

where, as above, $\alpha_2(\cdot)$ is a $\mathcal{K}$-class function. In addition, the terminal cost function $V_f(\cdot)$ satisfies locally a usual condition for robust stabilization,

which is expressed by the requirement that for all $x \in \mathbb{X}_f$ and all $w \in \mathbb{W}$, it holds that

$$V_f\left(f\left(x, \kappa_f\left(x\right), w\right)\right) - V_f\left(x\right) \leq -\ell\left(x, \kappa_f\left(x\right)\right). \tag{16}$$

The cost function $V_N(\cdot, \cdot, \cdot)$ is defined, for all $x \in \mathbb{X}$, all Π_{N-1}, and all $\mathbf{w}_{N-1} := \{w_0, w_1, \ldots, w_{N-1}\}$, by

$$V_N\left(x, \Pi_{N-1}, \mathbf{w}_{N-1}\right) := \sum_{k=0}^{N-1} \ell\left(x_k, u_k\right) + V_f\left(x_N\right), \tag{17}$$

where, for notational simplicity, $u_k := \pi_k(x_k)$ and $x_k := x_k(x, \Pi_{N-1}, \mathbf{w}_{N-1})$ denote the solution of (1) when the initial state is x, control policy is Π_{N-1}, and uncertainty realization is $\mathbf{w}_{N-1}$.

The exact ROC: In view of the uncertainty, the corresponding exact ROC problem $\mathbb{P}_N(x)$, for any $x \in \mathbb{X}$, aims to optimize the "worst-case" performance so that it takes the form of an infinite-dimensional minimaximization:

$$J_N\left(x, \Pi_{N-1}\right) := \max_{\mathbf{w}_{N-1} \in \mathbb{W}^N} V_N\left(x, \Pi_{N-1}, \mathbf{w}_{N-1}\right),$$

$$V_N^0\left(x\right) := \min_{\Pi_{N-1} \in \Pi_{N-1}(x)} J_N\left(x, \Pi_{N-1}\right),$$

$$\Pi_{N-1}^0\left(x\right) \in \arg \min_{\Pi_{N-1} \in \Pi_{N-1}(x)} J_N\left(x, \Pi_{N-1}\right), \tag{18}$$

where $\mathbf{\Pi}_{N-1}(x)$ denotes the set of the constraint admissible control policies defined, for all $x \in \mathbb{X}$, by

$$\Pi_{N-1}\left(x\right) := \{\Pi_{N-1} : \text{conditions (5)–(7) hold}\}. \tag{19}$$

The value function $V_N^0(\cdot)$ might not admit a unique optimal control policy, so that $\Pi_{N-1}^0(\cdot)$ represents a selection from the set of optimal control policies (this selection is usually induced by a numerical solver employed for the online calculations). The effective domain $\mathcal{X}_N$ of the value function $V_N^0(\cdot)$ and associated optimal control policy $\Pi_{N-1}^0(\cdot)$ is given by

$$\mathcal{X}_N := \{x \in \mathbb{R}^n : \Pi_{N-1}(x) \neq \emptyset\}. \tag{20}$$

and is known in the literature as the N-step min–max controllable set to a target set $\mathbb{X}_f$. Within the considered setting, the set $\mathcal{X}_N$ is a compact subset of $\mathbb{X}$ such that $\mathbb{X}_f \subseteq \mathcal{X}_N$.

The exact RMPC: The exact RMPC synthesis requires online solution of the minimaximization (18) in order to implement numerically the control law $\pi_0^0(\cdot)$. The control law $\pi_0^0(\cdot)$ is well defined for all $x \in \mathcal{X}_N$, and it induces the controlled uncertain dynamics specified, for all $x \in \mathcal{X}_N$, by

$$x^+ \in \mathcal{F}\left(x\right), \mathcal{F}\left(x\right) := \{f\left(x, \pi_0^0\left(x\right), w\right) : w \in \mathbb{W}\}. \tag{21}$$

Within the considered setting, the exact RMPC law $\pi_0^0(\cdot)$ renders the N-step min–max controllable set $\mathcal{X}_N$ robust positively invariant. Namely, for all $x \in \mathcal{X}_N$, it holds that

$$\mathcal{F}\left(x\right) \subseteq \mathcal{X}_N \subseteq \mathbb{X} \text{ and } \pi_0^0\left(x\right) \in \mathbb{U}. \tag{22}$$

Furthermore, the associated value function $V_N^0(\cdot) : \mathcal{X}_N \rightarrow \mathbb{R}_+$ is, by construction, a Lyapunov certificate verifying the robust asymptotic stability of the generalized origin $\mathbb{X}_{\mathcal{O}}$ for the controlled uncertain dynamics (21) with the basin of attraction being equal to the N-step min–max controllable set $\mathcal{X}_N$. More precisely, for all $x \in \mathcal{X}_N$, it holds that

$$\alpha_1\left(\text{dist}\left(\mathbb{X}_{\mathcal{O}}, x\right)\right) \leq V_N^0\left(x\right) \leq \alpha_3\left(\text{dist}\left(\mathbb{X}_{\mathcal{O}}, x\right)\right), \tag{23}$$

where $\alpha_3(\cdot)$ is a suitable $\mathcal{K}$-class function, while for all $x \in \mathcal{X}_N$ and all $x^+ \in \mathcal{F}(x)$, it holds that

$$V_N^0\left(x^+\right) - V_N^0\left(x\right) \leq -\alpha_1\left(\text{dist}\left(\mathbb{X}_{\mathcal{O}}, x\right)\right). \tag{24}$$

Clearly, under fairly natural conditions, the exact RMPC synthesis induces rather strong structural properties, but the associated computational complexity is overwhelming. However, in the above overview, the effects of the uncertainty have been "dissected" and the "basic building blocks" employed for the exact RMPC synthesis have been clearly identified. In turn, this step-by-step overview suggests indirectly the meaningful

and simplifying approximations in order to enhance computational practicability.

Computational Simplifications

The computational intractability of the exact RMPC synthesis can be tackled by considering suitable parameterizations of control policy Π_{N-1} and associated state and control tubes $\mathbf{X}_N$ and $\mathbf{U}_{N-1}$ and by adopting computationally simpler performance criteria.

The core simplification is the use of finite-dimensional parameterization of control policy. The control policy should be suitably parameterized so as to allow for the utilization of both the least conservative generalized state and control predictions and a range of simpler, but sensible, cost functions.

The explicit form of the exact state and control tubes is usually highly complex, and it is computationally beneficial to employ, when feasible, the implicit representation of the possible sets of predicted state and control actions. An alternative is to utilize outer-bounding approximations of the exact state and control tubes; these are obtained by making use of simpler sets that usually admit finite-dimensional parameterizations. In the latter case, the exact set dynamics of the state and control tubes given by (5) are usually relaxed to set inclusions

$$\{x_0\} \subseteq X_0, \text{ and, } F(X_k, \pi_k) \subseteq X_{k+1}$$
$$\text{and } G(X_k, \pi_k) \subseteq U_k.$$

The generalized origin, i.e., the minimal robust positively invariant set $\mathbb{X}_{\mathcal{O}}$, is an integral component for the analysis. Its explicit computation is rather demanding and, hence, its use for the online calculations might not be convenient. A computationally feasible alternative is to deploy the terminal constraint set $\mathbb{X}_f$ as a "relaxed form" of the generalized origin; this is particularly beneficial when the local control function $\kappa_f(\cdot)$ is optimal w.r.t. infinite horizon cost associated with the unconstrained version of the system (1).

The performance requirements should be carefully prioritized and modified when necessary, in such a way so as to be expressible by the cost functions that do not require intractable minimax optimization but still ensure that the associated value function verifies the robust stability and attractivity of the generalized origin $\mathbb{X}_{\mathcal{O}}$ or the terminal constraint set $\mathbb{X}_f$.

The outlined guidelines have played a pivotal role in devising a number of theoretically sound and computationally efficient parameterized RMPC syntheses within the setting of linear control systems subject to additive disturbances and polytopic constraints. In this linear–polytopic setting, the state transition map $f(\cdot, \cdot, \cdot)$ of (1) is linear:

$$f(x, u, w) = Ax + Bu + w, \qquad (25)$$

where the matrix pair $(A, B) \in \mathbb{R}^{n \times n} \times \mathbb{R}^{n \times m}$ is assumed to be known and strictly stabilizable. The local control function $\kappa_f(\cdot)$ and associated local uncertain dynamics are linear:

$$u = Kx \text{ and } x^+ = (A + BK)x + w. \quad (26)$$

The matrix $K \in \mathbb{R}^{m \times n}$ is designed offline and is such that the eigenvalues of the matrix $A + BK$ are strictly inside of the unit circle. The constraint sets $\mathbb{X}$ and $\mathbb{U}$ are polytopes (A polytope is a convex and compact set specified by finitely many linear/affine inequalities, or by a convex hull of finitely many points) in $\mathbb{R}^n$ and $\mathbb{R}^m$ that contain the origin in their interior. The uncertainty constraint set $\mathbb{W}$ is a polytope in $\mathbb{R}^n$ that contains the origin.

The terminal constraint set $\mathbb{X}_f$ is the maximal robust positively invariant for $x^+ = (A+BK)x + w$ and constraint set $(\mathbb{X}_K, \mathbb{W})$ where $\mathbb{X}_K := \{x \in \mathbb{X} : Kx \in \mathbb{U}\}$. The set $\mathbb{X}_f$ is assumed to be a polytope in $\mathbb{R}^n$ that contains the generalized origin $\mathbb{X}_{\mathcal{O}}$ (which is the minimal robust positively invariant set for $x^+ = (A + BK)x + w$ and constraint set $(\mathbb{X}_K, \mathbb{W})$) in its interior.

It has recently been demonstrated that the major simplified RMPC syntheses in the linear–polytopic setting employ control policies within the class of separable state feedback (SSF) control policies (Raković 2012). More precisely, the predictions of the overall states x_k and

associated control actions u_k are parameterized in terms of the predictions of the partial states $x_{(j,k)}$, $j = 0, 1, \ldots, k$ and partial control actions $u_{(j,k)}$, $j = 0, 1, \ldots, k$ via

$$x_k = \sum_{j=0}^{k} x_{(j,k)} \text{ and } u_k = \sum_{j=0}^{k} u_{(j,k)}, \qquad (27)$$

where, for notational simplicity, $u_k := \pi_k(x_k)$ and $u_{(j,k)} := \pi_{(j,k)}(x_{(j,k)})$. To ensure the dynamical consistency with (25), the predicted partial states $x_{(j,k)}$ evolve according to

$$x_{(j,k+1)} = Ax_{(j,k)} + Bu_{(j,k)}, \qquad (28)$$

(for $j = 0, 1, \ldots, N - 1$ and $k = j, j + 1 \ldots, N - 1$), while the "partial" initial conditions $x_{(k,k)}$ satisfy

$$x_{(0,0)} = x \text{ and} \qquad (29a)$$

$$x_{(k,k)} = w_{k-1} \text{ for } k = 1, 2, \ldots, N. \qquad (29b)$$

As elaborated on in Raković (2012) and Raković et al. (2012), the utilization of the SSF control policy allows for:

- The deployment of the highly desirable implicit representation of the exact state and control tubes induced by the SSF control policy. This implicit representation is parameterized via $O(N^2)$ decision variables.
- The numerically convenient formulation of the robust constraint satisfaction via $O(N^2)$ linear/affine inequalities and equalities.
- The computationally efficient minimization of an upper bound of the "worst-case" cost for which the stage and terminal cost functions are specified in terms of the weighted distances from the terminal constraint set $\mathbb{X}_f$ and the associated control set $\mathbb{U}_f = K\mathbb{X}_f$.

As shown in Raković (2012) and Raković et al. (2012), the RMPC control laws, based on the use of the SSF control policy, can be implemented online by solving a standard convex optimization problem whose complexity (in terms of the numbers of decision variables and affine inequalities and equalities) is $O(N^2)$. The corresponding

RMPC synthesis ensures directly that the terminal constraint set $\mathbb{X}_f$ is robustly exponentially stable, and it also induces indirectly the robust exponential stability of the generalized origin $\mathbb{X}_{\mathcal{O}}$.

The previously dominant control policy parameterizations include time-invariant affine state feedback (TIASF), time-varying affine state feedback (TVASF), and affine in the past disturbances feedback (APDF) control policies. All of these parameterizations are subsumed by the SSF control policy, as all of them induce additional structural restrictions on the parameterizations of the predicted state and control actions specified in (27) and on the associated dynamics given by (28), (29) and (30). In particular, the TIASF control policy (Chisci et al. 2001; Gossner et al. 1997) imposes structural restrictions that, for each relevant k,

$$u_{(j,k)} = Kx_{(j,k)} \text{ for } j = 1, 2, \ldots, k, \qquad (30)$$

where K is the local control matrix of (26). The TVASF control policy (Löfberg 2003) induces less restrictive requirements that, for each relevant k,

$$u_{(j,k)} = K_{(j,k)}x_{(j,j)} \text{ for } j = 1, 2, \ldots, k, \qquad (31)$$

where the matrices $K_{(j,k)} \in \mathbb{R}^{m \times n}$ are part of the decision variable. The APDF control policy (Goulart et al. 2006; Löfberg 2003) is an algebraic reparameterization of the TVASF control policy, which requires the conditions that, for each relevant k,

$$u_{(j,k)} = M_{(j,k)}x_{(j,k)} \text{ for } j = 1, 2, \ldots, k, \qquad (32)$$

where the matrices $M_{(j,k)} \in \mathbb{R}^{m \times n}$ are part of the decision variable. A comprehensive trade-off analysis between the quality of guaranteed structural properties and the associated computational complexity and a theoretically meaningful ranking of the existing RMPC syntheses in the linear–polytopic setting is reported in the recent plenary paper (Raković 2012). Therein, it is demonstrated that the dominant approach is the RMPC synthesis utilizing the SSF control policy

(Raković 2012) (also known as the parameterized tube MPC (Raković et al. 2012)).

Summary and Future Directions

The exact RMPC synthesis has reached a remarkable degree of theoretical maturity in the general setting. The corresponding theoretical advances are, however, accompanied with the impeding computational complexity. On the bright side of the things, a number of rather sophisticated RMPC synthesis methods, which are both computationally efficient and theoretically sound, have been developed for the frequently encountered linear–polytopic case.

The further advances in the RMPC field might be driven by the utilization of more structured types and models of the uncertainty. The challenge of devising a computationally efficient and theoretically sound RMPC synthesis might need to be tackled in several phases; the initial steps might focus on adequate RMPC synthesis for particular classes of nonlinear control systems. Finally, it would seem reasonable to expect that the lessons learned in the RMPC field might play an important role for the research developments in the fields of the stochastic and adaptive MPC.

Recommended Reading

The recent monograph (Rawlings and Mayne (2009)) provides an in-depth systematic exposure to the RMPC field and is also a rich source of relevant references. The invaluable overview of the theory and computations of the maximal and minimal robust positively invariant sets can be found in (Artstein and Raković (2008), Kolmanovsky and Gilbert (1998), Raković et al. (2005), and Blanchini and Miani (2008)). The important paper (Scokaert and Mayne (1998))

points out the theoretical benefits of the use of the control policy, but it also indicates indirectly the computational impracticability of the associated feedback min–max RMPC. The early tube MPC synthesis (Mayne et al. 2005) is both computationally efficient and theoretically sound, and it represents an important step forward in the linear–polytopic setting. The so-called homothetic tube MPC synthesis (Raković et al. 2013) is a recent improvement of the first generation of the tube MPC synthesis (Mayne et al. 2005), and it has a high potential to effectively handle the parametric uncertainty of the matrix pair (A, B). The current state of the art in the linear–polytopic setting is reached by the RMPC synthesis using the SSF control policy (Raković 2012; Raković et al. 2012). The output feedback RMPC synthesis in the linear–polytopic setting can be handled with direct extensions of the tube MPC syntheses (Mayne et al. 2009).

Abstract

This entry provides a brief summary of the synthesis and analysis tools that have been developed by the robust control community. Many software tools have been developed to implement the ma-

jor theoretical techniques in robust control. These software tools have enabled robust synthesis and analysis techniques to be successfully applied to numerous industrial applications.

Keywords

Integral quadratic constraint; Linear matrix inequality; Model uncertainty; Robust control toolbox; Structured singular values

Introduction

Robust control is a methodology to address the effect of uncertainty on feedback systems. This approach includes techniques and tools to model system uncertainty, assess stability and/or performance characteristics of the uncertain system, and synthesize controllers for uncertain systems. The theory was developed over a number of years. The foundational results can be found in classical papers Packard and Doyle (1993a), Desoer et al. (1980), Doyle (1978, 1982), Doyle et al. (1989), Doyle and Stein (1981), Megretski and Rantzer (1997), Safonov (1982), Willems (1971), and Zames (1981) and more recent textbooks Boyd et al. (1994), Desoer and Vidyasagar (2008), Dullerud and Paganini (2000), Francis (1987), Skogestad and Postlethwaite (2005), Vidyasagar (1985), and Zhou et al. (1996). It should be emphasized that this entry is not meant to be a survey and more complete references to the literature can be found in the cited textbooks. The remainder of this entry discusses the main theoretical and computational tools for robust synthesis and robustness analysis.

Notation

$\mathbf{R}$ and $\mathbf{C}$ denote the set of real and complex numbers, respectively. $\mathbf{R}^{m \times n}$ and $\mathbf{C}^{m \times n}$ denote the sets of $m \times n$ matrices whose elements are in $\mathbf{R}$ and $\mathbf{C}$, respectively. A single superscript index is used for vectors, e.g., $\mathbf{R}^n$ denotes the set of $n \times 1$ vectors whose elements are in $\mathbf{R}$. For a

matrix $M \in \mathbf{C}^{m \times n}$, M^T denotes the transpose and M^* denotes the complex conjugate transpose. A matrix M is Hermitian (Skew-Hermitian) if $M = M^*$ ($M = -M^*$). The maximum singular value of a matrix M is denoted by $\bar{\sigma}(M)$. The trace of a matrix M, denoted $tr[M]$, is the sum of the diagonal elements. $M = M^*$ is a positive semidefinite matrix, denoted $M \succeq 0$, if all eigenvalues are nonnegative. $M = M^*$ is negative semidefinite, denoted $M \preceq 0$, if $-M \succeq 0$. $\mathcal{L}_2^n[0, \infty)$ is the space of functions $u : [0, \infty) \to \mathbf{R}^n$ satisfying $\|u\| < \infty$ where $\|u\| := \left[\int_0^\infty u(t)^T u(t) \, dt \right]^{0.5}$. For $u \in \mathcal{L}_2^n[0, \infty)$, u_T denotes the truncated function $u_T(t) = u(t)$ for $t \leq T$ and $u(t) = 0$ otherwise. The extended space, denoted $\mathcal{L}_{2e}$, is the set of functions u such that $u_T \in \mathcal{L}_2$ for all $T \geq 0$. The Fourier transform $\hat{v} := \mathcal{F}(v)$ maps the time domain signal $v \in \mathcal{L}_2^n[0, \infty)$ to the frequency domain by

$$\hat{v}(j\omega) := \int_0^\infty e^{-j\omega t} v(t) dt \qquad (1)$$

Capital letters are used to represent dynamical systems. For linear systems, the same letter is used to represent the system, its convolution kernel, as well as its frequency-response function. Lowercase letters denote time-signals, and ω represents the continuous-time frequency variable. For an $m \times n$ system G, define the H_∞ and H_2 norms as $\|G\|_\infty = \sup_\omega \bar{\sigma}(G(j\omega))$ and $\|G\|_2 = \sqrt{\frac{1}{2\pi} \int_{-\infty}^\infty tr[G(j\omega)^* G(j\omega)] d\omega}$. The $\mathcal{L}_1$ norm of G is defined as $\|G\|_1 = \max_{1 \leq i \leq m} \sum_{j=1}^n \int_0^\infty |g_{ij}(t)| dt$ where $g_{ij}(t)$ is the response of the ith output due to a unit impulse in the jth input. The entry describes continuous-time systems. Most results carry over, in a similar form, to discrete-time systems.

Theoretical Tools

Uncertainty Modeling

In order to analyze and/or design for the degrading effects of uncertainty, it is imperative that explicit models of uncertainty be characterized. Two distinct forms of uncertainty are considered: signal uncertainty and model uncertainty. Signal uncertainty represents external signals (plant disturbances, sensor noise, reference signals) as sets of time functions, with explicit descriptions. For example, a particular reference input might be characterized as belonging to the set $\left\{ \frac{4}{2s+1} d : d \in \mathcal{L}_2, \|d\|_2 \leq 1 \right\}$. This set is often referred to as a *weighted ball in* $\mathcal{L}_2$. The transfer function $\frac{4}{2s+1}$ is called a *weighting function* and it shapes the normalized signals d, in a manner that its output represents the actual traits of the reference inputs that occur in practice.

Model uncertainty represents unknown or partially specified gains (more generally, operators) that relate pairs of signals in the model. For example, z and w are signals within a model and are related by an operator $\mathcal{N}$ as $w = \mathcal{N}(z)$. Typical partial specifications either constrain $\mathcal{N}$ to be drawn from a specified set or describe the set of signals (w, z) that $\mathcal{N}$ allows. An *uncertain parameter* δ is modeled as time-invariant (i.e., constant), belonging to the interval $[a, b]$ and relating z and w as $w(t) = \delta z(t)$. An *uncertain linear dynamic element*, Δ is modeled as linear, time-invariant, causal system, described by a convolution kernel δ whose frequency-response function (i.e., Fourier transform) satisfies $\max_\omega \left| \hat{\delta}(j\omega) \right| \leq 1$, and relating z and w as $w = \delta \star z$. More generally, consider an $\mathcal{L}_2$ bounded, causal operator, mapping $\mathcal{L}_{2,e} \to \mathcal{L}_{2,e}$ relating the signals as $w = \Delta(z)$. The behavior of Δ is unknown but constrained by a family of multipliers, $\{\Pi_\alpha\}_{\alpha \in \mathcal{A}}$. Specifically, each Π_α is a Hermitian, matrix-valued function of frequency, and for any $z \in \mathcal{L}_2$, the mapping Δ is known to satisfy

$$\int_{-\infty}^\infty \begin{bmatrix} \hat{z}(j\omega) \\ \hat{w}(j\omega) \end{bmatrix}^* \Pi_\alpha(\omega) \begin{bmatrix} \hat{z}(j\omega) \\ \hat{w}(j\omega) \end{bmatrix} d\omega \geq 0$$

This is called an *integral quadratic constraint* (IQC) description of Δ, as the input/output pairs of Δ satisfy a family of quadratic, integral constraints. These different descriptions of model uncertainty are related. For example, if $w(t) = \delta z(t)$, with $w(t) \in \mathbf{R}^n$ and $z(t) \in \mathbf{R}^n$, and $\delta \in \mathbf{R}, |\delta| \leq 1$, then for any Hermitian-valued $X : \mathbf{R} \to \mathbf{C}^{n \times n}$ with $X(\omega) \succeq 0$ for all $\omega \in \mathbf{R}$ and Skew-Hermitian $Y : \mathbf{R} \to \mathbf{C}^{n \times n}$,

$$\int_{-\infty}^{\infty} \begin{bmatrix} \hat{z}(j\omega) \\ \hat{w}(j\omega) \end{bmatrix}^* \begin{bmatrix} X(\omega) & Y(\omega) \\ Y^*(\omega) & -X(\omega) \end{bmatrix} \begin{bmatrix} \hat{z}(j\omega) \\ \hat{w}(j\omega) \end{bmatrix} d\omega$$
$$= \int_{-\infty}^{\infty} \hat{z}^*(j\omega) \left[(1 - \delta^2) X(\omega) \right] \hat{z}(j\omega) d\omega$$

which is always $\succeq 0$. Hence, the *uncertain parameter* can be recast as an operator satisfying an infinite family of IQCs. Nonlinear operators may also satisfy IQCs and it is common to "model" known nonlinear elements (e.g., saturation) by enumerating IQCs that they satisfy (Megretski and Rantzer 1997). An *uncertain dynamic model* is made up of an interconnection of these uncertain elements with a known (usually) linear system G.

Performance Metric

The main goal of robustness analysis is to assess the degrading effects of uncertainty. For this, a concrete notion of performance is needed, resulting in a mathematical/computational exercise to quantify the average or worst-case effects of the two types of uncertainty, signal and model, described earlier. In the robust control framework, adequate performance is characterized in terms of the variability of possible behavior of particular signals. For instance, in the presence of reference inputs and disturbance inputs, as well as parameter uncertainty, it is required that tracking errors (e) and control inputs (u) remain small. A common measure of smallness is the $\mathcal{L}_2$ norm of signals. Typically, frequency-dependent weighting functions are used to preferentially weight one frequency range over another and/or to weight one signal relative to another. In this way, adequate performance be defined as $\|W \begin{bmatrix} e \\ u \end{bmatrix}\|_2 \leq 1$, where W is a stable, linear system, called the "output" weighting function. Weighting functions are often used to transform a collection of performance objectives into a single norm bound objective in the robust control framework.

Robustness Analysis

Robustness analysis refers to the task of ascertaining the stability and/or performance characteristics of the uncertain system, given the

limited knowledge about the uncertain information. The main result from Megretski and Rantzer (1997) concerns the stability of the interconnection shown in Fig. 1, where G is a known, stable, linear system and Δ is an operator that satisfies the IQC defined by Π. Under some important technical conditions, the theorem states "if there exists an $\epsilon > 0$ such that

$$\begin{bmatrix} G(j\omega) \\ I \end{bmatrix}^* \Pi(\omega) \begin{bmatrix} G(j\omega) \\ I \end{bmatrix} \preceq -\epsilon I \quad (2)$$

for all $\omega \in \mathbf{R}$, then the interconnection is stable." Stability here refers to finite $\mathcal{L}_2$ gain from inputs (r_1, r_2) to loop signals (u_1, u_2).

Multiple IQCs satisfied by Δ can be incorporated into the analysis. In particular, assume that Δ satisfies the IQCs defined by the multipliers $\{\Pi_k\}_{k=1}^N$. Then Δ satisfies the IQC defined by any multiplier of the form $\Pi^\alpha := \sum_{k=1}^N \alpha_k \Pi_k$ where $\alpha_k \geq 0$. The stability test amounts to a semi-infinite, semidefinite feasibility problem: find nonnegative scalars $\{\alpha_k\}_{k=1}^N$ such that for some $\epsilon > 0$,

$$\begin{bmatrix} G(j\omega) \\ I \end{bmatrix}^* \Pi^\alpha(\omega) \begin{bmatrix} G(j\omega) \\ I \end{bmatrix} \preceq -\epsilon I \quad (3)$$

for all $\omega \in \mathbf{R}$. This infinite family of matrix inequalities (one for each frequency) can be equivalently expressed as a finite-dimensional linear matrix inequality (LMI) under some additional restrictions.

The structured singular value (μ) approach provides an alternative robust stability test in the case of only linear, time-invariant uncertainty
Robust Synthesis and Robustness Analysis Techniques and Tools, Fig. 1 Feedback interconnection for IQC stability test

(parametric or dynamic). Suppose Δ is drawn from a set of matrices, $\Delta \subseteq \mathbf{C}^{m \times n}$ of the form

$$\Delta = \big\{ \text{diag} \big[\delta_1^r I_{t_1}, \ldots, \delta_V^r I_{t_V}, \\ \delta_1^c I_{r_1}, \ldots, \delta_S^c I_{r_S}, \Delta_1, \ldots, \Delta_F \big] : \\ \delta_k^r \in \mathbf{R}, \delta_i^c \in \mathbf{C}, \Delta_j \in \mathbf{C}^{m_j \times n_j} \big\}$$

The inclusion of complex-valued, uncertain matrices within Δ may seem unusual and hard to motivate. However, in terms of their effect on stability, these are equivalent to the *uncertain linear dynamic element* introduced earlier in the *Uncertainty Modeling* section. This is discussed in more detail in the entry ▶ Structured Singular Value and Applications: Analyzing the Effect of Linear Time-Invariant Uncertainty in Linear Systems.

Using the Nyquist stability criterion, the (G, Δ) interconnection is stable for all $\Delta \in \Delta$, with $\bar{\sigma}(\Delta) < \beta$ if and only if G is stable, and

$$\det(I - G(j\omega)\Delta) \neq 0$$

for all $\Delta \in \Delta$ with $\bar{\sigma}(\Delta) < \beta$ and all $\omega \in \mathbf{R}$ including $\omega = \infty$. The importance of the nonvanishing determinant condition warrants a definition of its own, the *structured singular value*. For a matrix $M \in \mathbf{C}^{n \times m}$, and Δ as given, define

$$\mu_{\Delta}(M) := \frac{1}{\min \{\bar{\sigma}(\Delta) : \Delta \in \Delta, \det(I - M\Delta) = 0\}}$$

unless no $\Delta \in \Delta$ makes $(I - M\Delta)$ singular, then $\mu_{\Delta}(M) := 0$. In this parlance, the (G, Δ) interconnection is stable for all $\Delta \in \Delta$, with $\bar{\sigma}(\Delta) < \beta$ if and only if

$$\mu_{\Delta}(G(j\omega)) \leq \frac{1}{\beta}$$

for all $\omega \in \mathbf{R}$ including $\omega = \infty$.

In summary, the structured singular value approach employs a Nyquist-based argument, resulting in a nonvanishing determinant condition, which must hold over all frequency and all possible frequency-response values of the uncertain elements. However, checking the nonvanishing determinant is difficult, and sufficient conditions,

in the form of semidefinite programs (Doyle 1982; Fan et al. 1991) to ensure this are derived. This results in semidefinite feasibility problems which must hold at all frequencies. It is common to verify these only on a finite grid of frequencies, which is equivalent to ensuring that the closed-loop poles cannot migrate across the stability boundary at these frequencies. Semidefinite programs can be defined which carve out intervals around these fixed frequencies to completely guarantee stability.

Robust Synthesis

Synthesis refers to the mathematical design of the control law. The nominal synthesis problem (with no uncertainty) is formulated using the generic feedback structure shown in Fig. 2. The various signals in the diagram are the control inputs u, measurements y, exogenous disturbances d, and regulated variables e. P is a generalized plant that contains all information required to specify the synthesis problem. This includes the dynamics of the actual plant being controlled as well as any frequency domain weights that are used to specify the performance objective. The objective of an optimal control problem is to synthesize a controller K that minimizes the closed-loop (e.g., H_2, H_∞, $\mathcal{L}_1$) norm from disturbances (d) to regulated variables (e), i.e., solve

$$\min_{\text{allowable } K} \|F_L(P, K)\|$$

where $F_L(P, K)$ denotes the system obtained by closing the controller K around the lower loop of P. The H_2, H_∞, and $\mathcal{L}_1$ optimal control problems refer to the choice of the specific norm $\|F_L(P, K)\|$ used to specify the performance. A generalization of the H_∞ performance objective is simply to require that the closed-loop map from $d \to e$ satisfy an IQC defined by a given multiplier Π, called the performance multiplier, Apkarian and Noll (2006). The H_2, H_∞ and $\mathcal{L}_1$ optimal control problems formulated as in Fig. 2 only involve signal uncertainty. In other words, these design problems do not explicitly account for the effects of model uncertainty.
Robust Synthesis and Robustness Analysis Techniques and Tools, Fig. 2 Feedback interconnection for H_2, H_∞, and $\mathcal{L}_1$ optimal control

Robust Synthesis and Robustness Analysis Techniques and Tools, Fig. 3 Feedback interconnection for μ synthesis

Robust synthesis refers to control design that explicitly accounts for model uncertainty. It is usually formulated as a worst-case optimization, where the controller is chosen to minimize the worst-case effect of the signal and model uncertainty, loosely

$$\min_{\text{allowable } K} \max_{\text{allowable } d, \Delta} \|T(d, \Delta, K)\|$$

where d is a set of exogenous disturbances and Δ corresponds to the model uncertainty set. T represents the closed-loop relationship between d, Δ and the controller K. μ-synthesis is a specific technique developed to synthesize control algorithms which achieve robust performance, i.e., performance in the presence of signal and model uncertainty. The objective of μ-synthesis is to minimize over all stabilizing controllers K, the peak value of $\mu_\Delta (F_L(P, K))$ of the closed-loop transfer function defined by the interconnection in Fig. 3. P is the generalized plant model. The Δ block is the uncertain element from the set $\boldsymbol{\Delta}$, which parameterizes all of the assumed model uncertainty in the problem. The μ-synthesis optimization has high computational complexity (so-called NP-hard problem), though practical algorithms and software have been developed to design controllers using this control technique (Balas et al. 2013). Alternative robust synthesis approaches exist and often involve nonlinear optimization algorithms (Apkarian and Noll 2006). Drastic simplification regarding the models and uncertainty can be made resulting in problems that can be solved using LMI and

semidefinite programming techniques (Boyd and Barrat 1991; Boyd et al. 1994).

Computational Tools

The MATLAB Robust Control Toolbox is a commercially available software product that is part of the Mathworks control product line. It is tightly integrated with Control System Toolbox and Simulink products (Balas et al. 2013). The Robust Control Toolbox includes tools to analyze and design multi-input, multi-output control systems with uncertain elements. The primary building blocks, called uncertain elements or atoms, are uncertain real parameters and uncertain linear, time-invariant objects. These can be used to create coarse and simple or detailed and complex descriptions of model uncertainty. The uncertain object data structure eliminates the need to generate models of uncertainty and control analysis and design problem formulations, thereby allowing the practicing engineer to apply advanced robust control theory to their applications. Functions are available to analyze the robust stability, robust performance, and worst-case performance of uncertain multivariable system models using the structured singular value, μ. The Robust Control Toolbox also includes multivariable

control synthesis tools to compute controllers that optimize worst-case performance and identify worst-case parameter values.

The IQC-Beta Toolbox is a publicly available robust analysis toolbox based on the IQC framework (Jönsson et al. 2004). A wide range of robust stability and performance analysis tests are available for uncertain, nonlinear, and time-varying systems. IQC-Beta is written in MAT-LAB and works seamlessly with the Control System Toolbox objects and basic interconnection functions. The Users manual nicely complements the literature on IQCs. The Computer Aided Control System Design package in Scilab, an open source numerical computation software, includes functionality for robustness analysis and the synthesis of robust control algorithms for multivariable systems (http://www.scilab.org/).

Conclusions

Robust control analysis and synthesis software tools are widely available and have been extensively used by industry since the late 1980s. The availability of software tools for robustness analysis and synthesis played a major role in their wide and ubiquitous adoption in industry. They have been successfully applied to a variety of applications including aircraft flight control, launch vehicles, satellites, compact disk players, disk drives, backhoe excavators, nuclear power plants, helicopters, thin film extrusion, gas- and diesel-powered engines, missile autopilots, heating and ventilation systems, process control, and active suspension systems.

Robustness Analysis of Biological Models

Steffen Waldherr[1] and Frank Allgöwer[2]
[1]Institute for Automation Engineering, Otto-von-Guericke-Universität Magdeburg, Magdeburg, Germany
[2]Institute for Systems Theory and Automatic Control, University of Stuttgart, Stuttgart, Germany

Abstract

Robustness analysis is the process of checking whether a system's function is maintained despite perturbations. Robustness analysis of biological models is typically applied to differential equation models of biochemical reaction networks. While robustness is primarily a yes-or-no question, for many applications in biological models, it is also desired to compute a quantitative robustness measure. Such a measure is usually defined to be the maximum size of perturbations that the system can still tolerate. In addition, it is often of interest to specifically compute fragile perturbations, i.e., perturbations for which the system loses its function.

Keywords

Biochemical reaction networks; Fragile perturbations; Parametric uncertainty; Robustness measure; Structural uncertainty

Introduction

In biological systems analysis, robustness is the property that a system maintains its function in the face of internal or external perturbations (Kitano 2007). For a robustness analysis, one therefore needs to specify the system to be analyzed, the function that should be maintained, and the perturbation class.

The models to which robustness analysis is applied are mostly differential equation models of biochemical reaction networks. They are generally written as

$$\dot{x} = S v(x), \qquad (1)$$

where $x \in \mathbb{R}^n$ is the vector of intracellular concentrations; $S \in \mathbb{R}^{n \times m}$ is the stoichiometric matrix, containing the information how the individual network components participate in the reactions; and $v(x) \in \mathbb{R}^m$ is the reaction rate vector, in most cases a nonlinear function of the concentrations x.

The biological functions that are being studied by robustness analysis are very broad, pertaining to the wide range of biological functions implemented by biochemical reaction networks. Specific problems being considered are:

1. The occurrence of qualitative dynamical patterns such as sustained oscillations or multistability, where the system converges to one of multiple stable steady states depending on initial conditions or external stimuli (Eissing et al. 2005; Ma and Iglesias 2002).
2. The steady-state concentration value for a subset of the biochemical network's components (Shinar and Feinberg 2010; Steuer et al. 2011).
3. Quantitative measures derived from the network's dynamics, for example, the period of sustained oscillations (Stelling et al. 2004).

For the perturbation classes, two approaches can be distinguished. In parametric robustness analysis, a parametrized biological model is given, and the perturbation consists in varying the values of the parameters away from their nominal value. In structural robustness analysis, perturbations to the interaction structure of the network or the functional form of the reaction rate functions $v(x)$ are considered. Robustness analysis with these perturbation classes is presented in more detail below.

The perturbation class is also relevant for two applications of robustness analysis which

R

go beyond simply deciding whether a system is robust or not. First, it is often of interest to get a better quantification of robustness than a binary decision. Then, it is common to define a robustness measure, which usually quantifies how large perturbations can be without affecting the system's function (Ma and Iglesias 2002; Morohashi et al. 2002). Such a measure requires an appropriate definition of the perturbation size. With parametric perturbations, norms in parameter space are often useful (Ma and Iglesias 2002; Waldherr and Allgöwer 2011). With structural perturbations, the proximity of interaction functions in function space (Breindl et al. 2011) or the number of changes in the interaction structure can be evaluated.

Second, one often desires to compute specific non-robust perturbations, i.e., perturbations within the given class for which the system loses the considered functionality. There is a close relation between non-robust perturbations and the robustness measure, in that the norm of the smallest non-robust perturbation is equal to the robustness measure. Yet, it is often easier to compute a robustness measure than a non-robust perturbation. Especially algorithms that give a lower bound on the robustness measure will usually not provide a non-robust perturbation.

An illustration of the key characteristics in robustness analysis is shown in Fig. 1. This also illustrates that any norm-based robustness

measure depends on the nominal situation, where no perturbation is present.

When performing robustness analysis on a mathematical model of the considered system, the potential mismatch between model and system has to be kept in mind. By comparing the mathematical analysis results to experimental observations, robustness analysis methods are also useful for the validation or invalidation of biological network models (Bates and Cosentino 2011).

Robustness Analysis with Parametric Perturbations

Robustness analysis with parametric perturbations is applied to parametrized differential equation models of biochemical reaction networks, which are described by an equation of the form

$$\dot{x} = Sv(x, \mu), \qquad (2)$$

where $\mu \in \mathbb{R}^p$ is a vector of parameters. Such parameters may, for example, represent the total expression level of proteins involved in the reaction network, where usually a large variability due to the stochastic process of gene expression occurs.

This entry focuses on two specific system functionalities for robustness with respect to parametric perturbations, the qualitative dynamical behavior, and the steady-state level of a subset of the network's components. These are particularly relevant for biological models: the dynamical behavior often represents qualitative biological regulatory mechanisms, whereas the steady-state level of network components with a downstream regulatory effect is important for the stimulus-response relation of a biological network.

The Qualitative Dynamical Behavior

Considering the qualitative dynamical behavior, it is of interest to distinguish situations of a globally stable equilibrium point, multiple locally stable equilibrium points, or sustained oscillations due to a limit cycle or more complex attractors. Since changes in these dynamical patterns
Robustness Analysis of Biological Models, Fig. 1 Illustration of key characteristics in robustness analysis

correspond to the occurrence of bifurcations in the model dynamics (2), this type of robustness analysis is closely related to bifurcation analysis. In the case of scalar, positive parameters μ, a corresponding robustness measure DOR has been defined by Ma and Iglesias (2002) as

$$DOR = 1 - \max\left\{ \frac{\check{\mu}}{\mu_0}, \frac{\mu_0}{\hat{\mu}}, 0 \right\}, \qquad (3)$$

where $\check{\mu}$ and $\hat{\mu}$ are the closest bifurcation points smaller and larger than μ, respectively. The robustness measure DOR is between 0 and 1 and indicates how much the parameter can be varied before reaching a bifurcation: for any multiplicative perturbation of less than $(1 - DOR)^{-1}$, no bifurcation will occur. A generalization to multiparametric models has been proposed in Waldherr and Allgöwer (2011): their robustness measure ϱ is defined as

$$\varrho = \sup\{\varrho \geq 1 \mid \text{no bifurcation occurs in the}$$
$$\text{hyperrectangle } [\varrho^{-1}\mu_0, \varrho\mu_0]\}. \qquad (4)$$

The measure ϱ directly gives the multiplicative parameter variation up to which no bifurcation occurs.

In general, the information required for a bifurcation-based robustness measure will only be available from a complete bifurcation analysis of the model. When restricting the types of bifurcations that are considered to bifurcations of equilibrium point, one can however check robustness by studying linear approximations at the system's equilibrium points. Since the reaction rates $v(x, \mu)$ are usually modeled as polynomial or rational functions, polynomial programming methods can be applied to compute a robustness measure (Waldherr and Allgöwer 2011) in this case.

The Steady-State Output Concentration

In biochemical network analysis, mostly linear outputs of the form

$$y = Cx, \qquad (5)$$

with $C \in \mathbb{R}^{q \times n}$ are considered. A common special case is that the rows of C are a subset of the rows of the identity matrix in $\mathbb{R}^n$, i.e.,

$$C = \left(e_i^{\mathrm{T}}\right)_{i \in \mathcal{I}_y}, \qquad (6)$$

and $\mathcal{I}_y \subset \{1, 2, \ldots, n\}$ is the index set defining the output concentrations.

A biochemical network has a robust steady-state output concentration, if the steady-state output $\bar{y}$ is independent of the parameters μ (Steuer et al. 2011). For a steady-state map $\bar{y} = h(\mu)$, this corresponds to the condition

$$h'(\mu) = 0. \qquad (7)$$

For the special case of an output given by (6), a sufficient and necessary condition for steady-state output robustness has been discovered by Steuer et al. (2011). The condition amounts to checking that a vector P, which describes the perturbation of the reaction rates under parameter variations, is in a subspace $\mathcal{I} = \operatorname{im} M + \ker S \operatorname{diag}(\alpha)$ for any α in the kernel of S, where M is a matrix composed of the normalized derivatives of the reaction rates with respect to the concentrations which do not appear in the output. A notable underlying assumption here is that the network's steady state does not undergo any local bifurcations within the considered parameter region, which directly relates back to the robustness analysis discussed in the previous section.

For the special case where parameters are the concentrations of conserved chemical species, a sufficient condition for steady-state output robustness has also been discovered by Shinar and Feinberg (2010). They propose the term *absolute concentration robustness* for this property. Here, the assumption that no local bifurcations occur within the considered parameter region is not required a priori but rather is also a consequence of the proposed condition.

Robustness Analysis with Structural Perturbations

Robustness analysis with parametric perturbations is based on the assumption that the reaction rate expressions are exact and that all perturbations are captured by parameter variations. This assumption can hardly be justified for many practical models, and an analysis with structural perturbations becomes necessary. Such analyses have discovered models which are very robust against parametric perturbations but nonrobust against structural perturbations (Jacobsen and Cedersund 2008).

The biological functions for which rigorous results on structural robustness are available are again related to the nonoccurrence of bifurcations in the model. For the restriction to local bifurcations of equilibria, linear systems theory offers efficient analysis tools for structural robustness.

In a first step, a structural perturbation of the network's interaction graph was suggested (Jacobsen and Cedersund 2008). This approach considers the network's Jacobian

$$A = S \frac{\partial v}{\partial x}(\bar{x}) \qquad (8)$$

evaluated at a steady state $\bar{x}$. The Jacobian is then perturbed to

$$\tilde{A} = \mathrm{diag}\, A + (A - \mathrm{diag}\, A)(I + \Delta), \qquad (9)$$

where $\mathrm{diag}\, A$ is the diagonal of A and Δ is a perturbation matrix, containing uncertain time-invariant linear systems as elements.

As an alternative approach, Waldherr et al. (2009) have suggested a structural perturbation of the reaction rate expressions. Thereby, the network's Jacobian is perturbed to

$$\tilde{A} = S \left(\frac{\partial v}{\partial x}(\bar{x}) + \Delta \right). \qquad (10)$$

In the case of real Δ, this perturbation simply corresponds to a change in the reaction rate slopes at steady state.

With both approaches, robustness analysis with structured singular values can be applied to test for changes in the local dynamics at the considered equilibrium point. This allows to evaluate a model's robustness against this type of structural perturbations and also yields non-robust perturbations.

Summary and Future Directions

Robustness analysis of biological models is well established in biological network theory. Mathematical methods rooted in systems and control are particularly beneficial for approaching this task.

While this entry focuses on models of biochemical reaction networks given by differential equations, the robustness analysis problem has also been studied in other model frameworks, for example, discrete dynamical models (Chaves et al. 2006). Yet, beyond simulation-based studies, robustness analysis is still an open problem in many practically relevant biological model classes. This concerns, for example, stochastic models or models on the cell population level.

In a similar manner, it will be important to extend the perturbation classes that are being considered and to include, for example, time-varying or other perturbations that are relevant for biological models. Concerning the biological function, most robustness analysis methods focus on the steady-state behavior. In the future, it will be of interest to also take, for example, the transient dynamics into account.

In linear systems theory, the concept of robust performance is well established. While efforts have been made to transfer that concept to biochemical networks (Doyle and Stelling 2005), it remains difficult to quantify performance of such networks, thus impeding the development of stringent robustness analysis tools. One of the reasons for this difficulty is certainly that biological performance is more naturally defined in the time domain than in the frequency domain, which narrows the conclusions that could be drawn from a direct application of classical robust performance analysis methods.

Robustness Issues in Quantum Control

Ian R. Petersen
School of Engineering and Information Technology, University of New South Wales, the Australian Defence Force Academy, Canberra, Australia

Abstract

Robust quantum control theory is concerned with the design of controllers for quantum systems taking into account uncertainty is the model of the system. The robust open-loop control of quantum systems is discussed in this entry. Also discussed is the robust stability analysis problem for quantum systems, and two forms of quantum small gain theorem are presented. In addition, the entry discusses the design of robust quantum feedback control systems.

Introduction

The control of systems whose dynamics are governed by the laws of quantum mechanics is the subject of quantum control theory. The topic of quantum control theory is covered in the companion article Petersen (2014). As in the case of classical control theory, the models used in quantum control are often subject to uncertainties. This motivates the study of robust quantum control, in which the quantum systems to be controlled are modeled as uncertain quantum systems, e.g., see Mabuchi and Khaneja (2005). A related problem is the problem of robust estimation and filtering for uncertain quantum systems, e.g., see Yamamoto and Bouten (2009). The issue of robust stability is particularly important in the case of quantum feedback control since in this case, there is always the possibility of instability. An important area of quantum control theory is open-loop quantum control; see Petersen (2014). Since uncertainties arise in the quantum system models being considered, the robustness of open-loop quantum control systems is also important, e.g., see Li and Khaneja (2009), Rabitz (2002), and Owrutsky and Khaneja (2012).

This entry surveys some of the important research results on robust quantum control which have arisen in various application areas. These include some recent results on robust open-loop control of quantum systems; see Zhang and Rabitz (1994). Also considered are some recent results on robust stability analysis results for uncertain quantum systems, which amount to quantum versions of the classical small gain theorem; see Petersen et al. (2012). Finally, the entry looks at robust quantum feedback controller design; see James et al. (2008) and Dong et al. (2009).

Robust Open-Loop Control of Quantum Systems

In the robust open-loop control of quantum systems, the quantum system is modeled in the Schrödinger picture. The models can be given either in terms of the Schrödinger equation for the system state $|\psi(t)\rangle$:

$$i\frac{\partial}{\partial t}|\psi(t)\rangle = \left[H_0 + \sum_{k=1}^{m} u_k(t)H_k\right]|\psi(t)\rangle \quad (1)$$

or the master equation for the system density operator ρ:

$$\dot{\rho}(t) = -i\left[\left(H_0 + \sum_{k=1}^{m} u_k(t)H_k\right), \rho(t)\right] \quad (2)$$

e.g., see Petersen (2014). In these equations, H_0 is the free Hamiltonian of the system and H_k are corresponding control Hamiltonians. In the robust open-loop control of quantum systems, these quantities are assumed to be uncertain and the control law $u_k(t)$ is to be designed to guarantee an adequate level of performance for all possible values of the uncertainties. Here, performance is measured in terms of the fidelity between the actual final state or density matrix of the system and the desired final state or density matrix, e.g., see Nielsen and Chuang (2000).

In the minimax optimal control approach to robust open-loop control of quantum systems, the uncertainties in the Hamiltonian are represented in terms of a vector quantity w which is subject to constraints. Then, the robust control problem is the minimax optimal control problem

$$\min_u \max_w J(u, w)$$

where $J(u, w)$ is a suitable cost function, and the problem is subject to the constraints defined by the system dynamics (1) and the constraints on the uncertainty w; see Zhang and Rabitz (1994). Some standard numerical procedures have been proposed to solve this minimax optimal control problem with applications in chemical physics; see Zhang and Rabitz (1994).

Related to the robust open-loop control of quantum systems is the control of inhomogeneous quantum ensembles. In this problem, the same control signal $u_k(t)$ is applied to a large number of quantum particles in an ensemble. Also, the Hamiltonians corresponding

to individual particles may have different parameter values, and so this problem is equivalent to a robust open-loop quantum control problem, e.g., see Li and Khaneja (2006). In studying this problem, the issue of controllability has been considered (see, e.g., Li and Khaneja 2009) as in the standard open-loop quantum control problem; see Petersen (2014). Also, numerical methods have been proposed for constructing an optimal control law for inhomogeneous ensembles, e.g., see Ruths and Li (2012) and Owrutsky and Khaneja (2012). This approach has arisen in applications to chemical physics.

Robustness Analysis for Uncertain Quantum Systems

The problem of robust stability analysis for uncertain quantum systems was considered in the paper D'Helon and James (2006) which was concerned with the feedback interconnection of two quantum optical systems as shown in Fig. 1. In this interconnection, each of the quantum systems is linear quantum optical systems described in the Heisenberg picture by linear quantum stochastic differential equations (QSDEs) of the form

$$
\begin{aligned}
\mathrm{d}x(t) &= Ax(t)\mathrm{d}t + B\mathrm{d}u(t); \\
\mathrm{d}y(t) &= Cx(t)\mathrm{d}t + D\mathrm{d}u(t); \quad (3)
\end{aligned}
$$
Robustness Issues in Quantum Control, Fig. 1 Feedback interconnection of two quantum optical systems

see James et al. (2008) and Petersen (2014) for more details on this class of quantum system models. Here, $x(t)$ are vector system variables which are operators on the underlying Hilbert space of the system. Also, the input and output fields are decomposed as $\mathrm{d}u(t) = \beta_u(t)\mathrm{d}t + \mathrm{d}\tilde{u}(t)$ and $\mathrm{d}y(t) = \beta_y(t)\mathrm{d}t + \mathrm{d}\tilde{y}(t)$ where $\beta_u(t)$, $\beta_y(t)$ denote the signal parts of the quantities $\mathrm{d}u(t)$, $\mathrm{d}y(t)$, respectively. Furthermore, $\mathrm{d}\tilde{u}(t)$, $\mathrm{d}\tilde{y}(t)$ denote the noise parts of the quantities $\mathrm{d}u(t)$, $\mathrm{d}y(t)$, respectively, e.g., see James et al. (2008). Such a system is stable and has a finite gain $g > 0$ if there exist constants $\mu > 0$ and $\lambda > 0$ such that

$$
\begin{aligned}
\int_0^t \langle \|\beta_y(\tau)\|^2 \rangle \mathrm{d}t &\leq \mu + \lambda t \\
&+ \int_0^t \langle \|\beta_u(\tau)\|^2 \rangle \mathrm{d}t \quad \forall t > 0;
\end{aligned}
$$

e.g., see D'Helon and James (2006) and James and Gough (2010). Here, $\langle \cdot \rangle$ denotes quantum expectation.

The two quantum optical systems shown in Fig. 1 are interconnected via beam splitters which are described by equations

$$
u_1 = \epsilon_1 w_1 - \sqrt{1 - \epsilon_1^2}\, y_2; \quad z_1 = \sqrt{1 - \epsilon_1^2}\, w_1 + \epsilon_1 y_2;
$$

$$
u_2 = \epsilon_2 w_2 - \sqrt{1 - \epsilon_2^2}\, y_1; \quad z_2 = \sqrt{1 - \epsilon_2^2}\, w_2 + \epsilon_2 y_1
$$

where $\epsilon_1 \in (0, 1)$ and $\epsilon_2 \in (0, 1)$ are given constants. The quantum small gain theorem established in D'Helon and James (2006) shows that if each of the quantum systems in Fig. 1 is stable and has finite gains $g_1 > 0$ and $g_2 > 0$ respectively such that $\sqrt{1 - \epsilon_1^2}\sqrt{1 - \epsilon_2^2}\, g_1 g_2 < 1$, then the feedback interconnected system will also be stable and have a finite gain. This result can be thought of as a stability robustness result if the first quantum system is regarded as the nominal quantum system and the second quantum system is regarded as being the uncertain part of the system subject to the given finite gain constraint.

An alternative approach to the robust stability analysis of uncertain quantum systems considers an uncertain quantum system described using the (S, L, H) description (see Petersen (2014) and

Gough and James (2009) for more details on this class of quantum systems). Here, the system Hamiltonian is described in terms of vectors of annihilation and creation operators a and $a^{\#}$, respectively, as

$$H = \frac{1}{2} \begin{bmatrix} a^{\dagger} & a^{T} \end{bmatrix} M \begin{bmatrix} a \\ a^{\#} \end{bmatrix} + \frac{1}{2} \tilde{\xi}^{\dagger} \Delta \tilde{\xi}$$

where M is a known complex Hermitian matrix describing the nominal Hamiltonian, Δ is a complex Hermitian uncertainty matrix subject to the norm bound $\|\Delta\| \leq \frac{2}{\gamma}$, and $\tilde{\xi} = E \begin{bmatrix} a \\ a^{\#} \end{bmatrix}$. Also, E is a known complex matrix describing the uncertainty structure. Furthermore, it is assumed that $S = I$ and the coupling operator vector L is such that $\begin{bmatrix} L \\ L^{\#} \end{bmatrix} = N \begin{bmatrix} a \\ a^{\#} \end{bmatrix}$ where N is a known complex matrix. This uncertain quantum system is robustly mean square stable if the H^{∞} norm bound condition

$$\left\| E \left(sI + iJM + \frac{1}{2} JN^{\dagger} JN \right)^{-1} JE^{\dagger} \right\|_{\infty} < \frac{\gamma}{2}$$

is satisfied where $J = \begin{bmatrix} I & 0 \\ 0 & -I \end{bmatrix}$; see Petersen et al. (2012).

Robust Feedback Control of Quantum Systems

Schrödinger Picture Approaches to Robust Measurement-Based Quantum Feedback Control

A number of results have appeared which use Schrödinger picture models (see Petersen 2014) in robust measurement-based quantum feedback control. These results are based on uncertain quantum system models of the form (1) or (2) and extend the results mentioned above by allowing for measurements of the quantum system in order to achieve improved robustness against uncertainties in the system Hamiltonian. For example, consider a quantum system of the form (1) with uncertainties in the system Hamiltonian. Then a

measurement feedback robust control scheme can be constructed which involves periodic projective measurements on the system. In a projective measurement of the quantum system (1), the state $|\psi(t)\rangle$ collapses to an eigenstate of H_0 corresponding to the measurement outcome obtained. The sliding mode control algorithm uses open-loop time optimal control (see Petersen 2014) to steer the state of the system back to a specified eigenstate of the system whenever a measurement is obtained which does not correspond to this desired eigenstate; see Dong and Petersen (2009). This desired eigenstate is referred to as the sliding mode domain, and the state of the system is guaranteed to stay within the sliding mode domain with a specified probability provided that the measurement sampling period in the proposed feedback control algorithm is chosen to be sufficiently fast; see Dong and Petersen (2009). In the case of two-level quantum systems, this sliding mode control approach is implemented using a Lyapunov method for open-loop quantum control to steer the system back to the sliding mode domain; see Petersen (2014) and Dong and Petersen (2012). In all of these cases, robustness is ensured by including uncertainty in the underlying quantum system models and then taking this into account in the design of the control laws and sampling period.

Another approach to the measurement-based robust quantum feedback control problem involves an extension of the robust open-loop control results considered in section "Robust Open-Loop Control of Quantum Systems." In this approach, robust open-loop control results are extended to solve the problem of stabilization of an ensemble of quantum particles; see Beauchard et al. (2012).

Heisenberg Picture Approaches to Robust Quantum Feedback Control

Consider a quantum linear system modeled in the Heisenberg picture by quantum stochastic differential equations (QSDEs) as follows:

$$\begin{aligned} dx(t) &= Ax(t)dt + Bdw(t); \\ dy(t) &= Cx(t)dt + Ddw(t); \end{aligned} \qquad (4)$$

see Petersen (2014) for details on this class of quantum system models which arises in the area of quantum optics. In the robust quantum feedback control problem, the matrices A, B, C, D may be uncertain and a feedback controller can be designed using the quantum H^∞ control approach to ensure that the resulting closed-loop system is robustly stable; see James et al. (2008). In the case of measurement-based feedback control, the controller is a classical system described by linear stochastic differential equations of the form

$$dx_K(t) = A_K x_k(t)dt + B_K dy(t)$$
$$\beta_u(t)dt = C_K x_k(t)dt; \qquad (5)$$

see Petersen (2014). In the case of coherent feedback control, the controller is another quantum linear system described by QSDEs of the form

$$dx_K(t) = A_K x_k(t)dt + B_K dy(t) + \bar{B}_K d\bar{w}_K(t)$$
$$dy_K(t) = C_K x_k(t)dt + \bar{D}_K d\bar{w}_K(t); \qquad (6)$$

see Petersen (2014).

In this approach to robust quantum feedback control, the uncertainty in the quantum system being controlled is represented by uncertainty in the matrix A as $A = \tilde{A} + \tilde{B}\Delta\tilde{C}$ where Δ is a constant but unknown uncertain matrix satisfying the bound $\Delta^T \Delta \leq I$. The controller, which may be either a classical controller or a coherent controller, is designed using the quantum H^∞ approach. Then the resulting closed-loop system will be robustly stable; see James et al. (2008). Similarly, in the case of uncertainty in the plant Hamiltonian matrix such as considered in section "Robustness Analysis for Uncertain Quantum Systems" or uncertainty in the form of an uncertain subsystem connected optically to the plant in feedback, also as considered in section "Robustness Analysis for Uncertain Quantum Systems," then the quantum H^∞ approach combined with the robust stability analysis results of section "Robustness Analysis for Uncertain Quantum Systems" shows that the quantum H^∞ method can also be used to design robustly stabilizing controllers in these cases.

Summary and Future Directions

To date there have been only a few papers published in the general area of robust quantum control. The results which were considered in this entry covered open-loop and feedback quantum control problems along with stability robustness analysis problems. A common theme in the results which were considered is that they were based on uncertain quantum mechanical models. It is expected that future research in this area will intensify as the use of feedback control becomes more prevalent in areas of experimental quantum technology.

Run-to-Run Control in Semiconductor Manufacturing

James Moyne
Mechanical Engineering Department, University of Michigan, Ann Arbor, MI, USA

Abstract

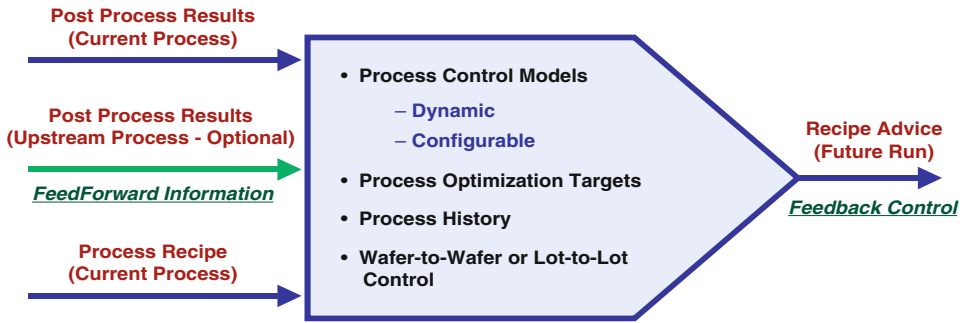
Run-to-run (R2R) control is a form of adaptive model-based process control that can be tailored to environments where the process is discrete, dynamic, and highly unobservable; this is characteristic of processes in the semiconductor manufacturing industry. It generally has, at its roots, a rather straightforward approach to adaptive model-based control such as a first-order linear plant model with moving average weighting applied to adapt the (zeroth-order) constant term in the model. Most of the complexity of R2R control science lies and will continue to lie in extensions to support practical application of R2R control in semiconductor manufacturing facilities of the future; these extensions include support for weighting and bounding of parameters, run-time modeling of a large number of disturbance types, and incorporating prediction information such as virtual metrology and yield prediction into the control solution.

Keywords

Adaptive control; Advanced process control (APC); EWMA control; Feed-forward and feedback control; Model-based control; R2R control; Run-to-run control; Single-threaded control; Virtual metrology; Wafer-to-wafer control; Yield prediction

Introduction

The semiconductor manufacturing industry involves the processing of semiconductor "wafers" using a variety of physical and chemical processes to produce dies or "chips" that contain a number of nanometer size features organized in layers. As feature sizes shrink, the industry must innovate to maintain acceptable product yield and throughput. One effective dimension of innovation that has been utilized since the early 1990s is model-based process control. The use of this technology in semiconductor manufacturing has been largely industry specific due to unique industry requirements and been given the name "run-to-run (R2R) control."

R2R control is defined as "...a form of discrete process and machine control in which the product recipe with respect to a particular machine process is modified ex situ, i.e., between


Run-to-Run Control in Semiconductor Manufacturing, Fig. 1 Input/output structure of a typical R2R control solution

machine 'runs,' so as to minimize process drift, shift, and variability" (Moyne et al. 2000). (The "recipe" is the group of process settings for a process or process step, e.g., temperature, flow, and pressure.) The term "R2R control" was coined in the early 1990s in the semiconductor industry as the industry struggled to come up with mechanisms to keep critical semiconductor manufacturing processes such as chemical vapor deposition (CVD), chemical mechanical polishing (CMP), and reactive ion etching (RIE) under control. The processes are highly unobservable and are subjected to a number of disturbances. However, many of these disturbances can be modeled or tracked as they create measurable shifts in the process (e.g., after a maintenance operation) or gradual drifts in the process (e.g., chamber wall "seasoning" of an etch process over time, resulting in polymer buildup on chamber walls, causes changes to the operational effectiveness of the tool). Process and product quality is generally assessed through metrology measurements made ex situ, i.e., after the process is complete; examples of post-process metrology parameters are wafer average deposited or removed film thickness and film uniformity. R2R control generally uses statistically developed models of tool process operation updated or "tuned" with process metrology feedback information on a "run-to-run" basis to keep the process under control and process quality high, in the face of these process drifts and shifts, as shown in Fig. 1. Note that the granularity of control could be wafer-to-wafer, or batch-to-batch ("lot-to-lot"), etc.

Run-to-Run Control Approach

Because the processes are highly unobservable and dynamic, rather simple model forms are usually employed with filtering techniques used to track process shift and drift. The most commonly utilized R2R controller in the industry is the exponentially weighted moving average (EWMA) controller. The algorithm uses a linear model with an additional constant term. (Equations will use the following notation: arrays of vectors will be capitals, vectors will be lower case, and indexing within a vector or matrix will be lower case with subscripts. In addition, the special subscript "t" will be reserved for time or run number information.)

$$Y = Ax + c \qquad (1)$$

where:

y = System output,
x = Input (Recipe),
A = Slope coefficients for equation,
c = Constant term for linear model.

Each output represents a target of control (usually measured by pre- and post-process metrology tools), and each input represents an adjustable parameter in the recipe.

$$y_1 = a_{11}x_1 + a_{12}x_2 + \ldots a_{1m}x_m + c_1$$

$$\cdots$$

$$y_n = a_{n1}x_1 + a_{n2}x_2 + \ldots a_{nm}x_m + c_n \qquad (2)$$

R

The models are generally developed by executing a design of experiments (DOE), where the process area is explored with respect to the allowed variation of the process inputs by processing wafers with various input settings (see, e.g., Box and Draper 1987). Statistical packages are then used to determine the base model of the form described in (1) at the normal process operating point. As the processes are dynamic, the base model is updated on a "run-to-run" basis to compensate for model error. The algorithm operates under the assumption that the underlying process is locally approximated by a first-order linear polynomial model in the form of equation (1) and that this polynomial model can be maintained near a local optimal point solely by updating the constant term "c."

The control process involves updating the model and then using that model to compute a recipe update. The model is updated by first comparing the actual process output, Y_t, to the model-predicted process output, AX_t. Using an EWMA filtering technique as an example, the constant term, c_t can be updated as follows:

$$c_t = \alpha(y_t - Ax_t) + (1 - \alpha)c_{t-1} \qquad (3)$$

where α is a weighting factor between 0 and 1, often called a "forgetting factor." Note that because of the additive nature of the EWMA series, the C_t calculation only requires knowledge (and storage) of the previous run measurements; this, combined with its relative simplicity, led to the widespread adoption of EWMA as the R2R controller filter of choice in this industry during the 1990s and early 2000s.

Once the model is updated, the process recipe is calculated. Since there are generally more inputs that can be tuned than outputs measured, the process is underdetermined and there is an infinite solution space. Approaches such as Lagrange multipliers are used to determine the solution that is closest to the previous solution (Moyne et al. 2000).

Many extensions and alternatives to this basic approach have been developed and deployed over the past 10 years. These include (1) the replacement of EWMA filtering with other approaches such as the more general Kalman filtering, (2) explicitly modeling drift (termed "predictor corrector"), (3) modeling updates to first-order terms (in the "A" matrix), and (4) leveraging phenomenological models that capture process knowledge in equation forms, customized and tuned with statistical data. Perhaps the most important extensions to the basic approach involve addressing the practical issues associated with control systems application in this area. For example, providing capabilities for addressing bounding, weighting, and granularity (e.g., integer) of input and output settings often requires much more programming effort than supporting the core algorithm (Moyne et al. 2000).

Current Status and Future Extensions

Over the past 10 years, R2R control has evolved from a value-added capability applied to a few processes, to a required component to achieve cost and productivity competitiveness in most processes in the semiconductor manufacturing industries (ITRS 2014). As part of this evolution, a number of common trends in the R2R control space have emerged:

Support for fab-wide reusable and reconfigurable solutions for R2R control: As the benefits of R2R control were proven across multiple processes in semiconductor fabrication facilities, the focus turned to reusable and reconfigurable integrated "fab-wide" solutions for R2R control. The event-based capabilities described in Chapter 9 of Moyne et al. (2000) were leveraged to provide these solutions as they allow for integration and configuration of R2R control solutions to the particular application environment. This event-based approach has also been used to integrate R2R control with other capabilities such as fault detection and classification (FDC), work scheduling, and "virtual metrology" (see below), to provide another level of benefits towards improved product yield and throughput (Khan et al. 2007; Moyne 2004, 2009).

Movement to more granular control: The evermore stringent requirements on product quality are being addressed in large part by a movement from batch-level control (often called "lot-based control" in this domain), to wafer-level control (usually called "wafer-to-wafer" (W2W) control), to within-wafer (WIW) control. Although the granularity has changed, the basic approach to control has not. It is important to note that the improvement in quality associated with this trend results mostly from the use of pre-(process) metrology to reject incoming product disturbances, rather than post metrology to address the dynamics of the plant model (ITRS 2014; Moyne et al. 2000).

Support for control across multiple recipes using "single-threaded control": Semiconductor manufacturing process control systems are characterized by a number of disturbance types that usually can be modeled as independent from the base process model and from each other. Perhaps the most common type of disturbance that is addressed is recipe or product change. When there is a change in product and related product recipe, a single-process model must be adjusted to capture this disturbance while maintaining knowledge of process drift and/or shift. Oftentimes this process disturbance can be modeled as a shift to the overall process. Thus, the process model of equation (1) can be adjusted to the following:

$$Y = Ax + c_1 + c_2 + c_3 + \ldots + c_n \quad (4)$$

where:

$c_1, c_2, \ldots c_{n-1}$ = constant terms associated with modeled disturbances such as product

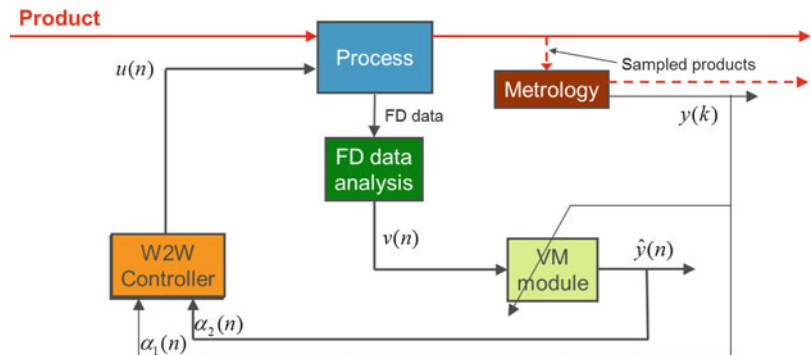
c_n = constant term associated with process dynamics (drift and shift)

$c_1 + c_2 + \ldots c_n = c$ in Eq. (1)

Approaches have been devised for the assessment of c_i associated with a particular disturbance type (Edgar et al. 2004; Zou 2013); the result is that a single-control model can be used across multiple product recipes and other disturbance types.

Enhancing R2R control with "virtual metrology": Ex-situ metrology plays a crucial role in semiconductor manufacturing as it is often the only source of product quality data before and after a process. However, given its high capital equipment cost and cycle time impact on critical processes, optimizing metrology by minimizing wasteful use and optimizing measurement value is important. Virtual metrology (VM) is a new technology rapidly gaining acceptance in the marketplace as an efficient and cost-effective way to optimize and augment metrology value. VM is a modeling and metrology prediction solution whereby process and product data, such as in situ fault detection (FD) information and upstream metrology information, is correlated to post-process metrology data. This same data can then be used to predict metrology information when conventional metrology data is not available (Cheng et al. 2011; Khan et al. 2007).

One of the uses of VM that is expected to become prominent over the next decade is in support of enhanced R2R control. As shown in Fig. 2, fault detection (FD) summary information

Run-to-Run Control in Semiconductor Manufacturing, Fig. 2 Virtual metrology enhanced R2R control


is used along with adaptive VM modeling to predict metrology information. The VM predictions are then used to fill in the measurement gaps in feed-forward and feedback control thus enabling wafer-to-wafer or even within-wafer control. One of the research challenges is to optimally tune the control to best utilize both the real and predicted metrology information. This requires that VM data contain information on predicted measurement data quality (Khan et al. 2007).

$u(n)$ Tunable process inputs

$v(n)$ FD summary information

$y(k)$ Metrology measurement data for measured wafers

$\hat{y}(n)$ Predicted metrology measurements for all wafers

$\alpha_1(n)$ Feedback filter coefficient for feedback of measured data

$\alpha_2(n)$ Feedback filter coefficient for feedback of predicted data

Movement towards interprocess and eventually fab-wide control: The generally accepted vision of the future of advanced process control (APC) in general is a fabrication-wide fully integrated solution that incorporates all of the APC capabilities (R2R control, FDC, fault prediction, and statistical process control) as well as predictive capabilities such as predictive scheduling, predictive maintenance, virtual metrology, and predictive yield (ITRS 2014). Opportunities for research and development exist with the integration of these technologies, especially as the powers of the predictive domain are tapped. For example, it is expected that R2R control will eventually incorporate predicted yield as a target with feedback to multiple coordinated process controllers (Moyne and Schulze 2010). Thus, the future of research in R2R control, while evolving, should remain strong in the coming years.

Summary and Future Directions

R2R control is a form of adaptive model-based process control that is tailored to environments where the process is discrete, dynamic, and highly unobservable; this is characteristic of processes in the semiconductor manufacturing industry. R2R control has evolved from a strictly research effort in the early 1990s to a required facility-wide capability in all of semiconductor manufacturing. It generally has, at its roots, a rather straightforward approach to adaptive model-based control. Most of the complexity of R2R control science lies and will continue to lie in extensions to support practical application of R2R control in semiconductor manufacturing facilities of the future.

The science of R2R control will continue to expand as the academic and industry communities look to incorporating capabilities that will allow R2R control to continue to be an integral part of the fabrication facility of the future. One key research direction over the next decade is the development of approaches for incorporating virtual metrology and yield prediction into control solutions. Other focus areas will likely include hybrids of R2R control and continuous process control, learning mechanisms for single-threaded control in "high-mix" environments where there are a large number of disturbances that should be modeled, phenomenological R2R control models, and model libraries that combine stochastic information with process physics and chemistry knowledge, control solutions that are more directly optimized to financial parameters such as yield and throughput, and R2R control solutions that incorporate other analysis capabilities, such as FDC, either algorithmically or via event-based control rule approaches. Each of these topics provides significant opportunity for research as well as benefit in application to semiconductor manufacturing facilities.

Sampled-Data H-Infinity Optimization

Tongwen Chen
Department of Electrical and Computer
Engineering, University of Alberta, Edmonton,
AB, Canada

Abstract

$\mathcal{H}_\infty$ optimization is central in robust control. When controllers are implemented by computers, sampled-data control systems arise. Designing $\mathcal{H}_\infty$-optimal controllers in purely continuous time or in purely discrete time is standard in robust control; in this entry, we discuss the process of sampled-data optimization, namely, designing digital controllers based on a continuous-time $\mathcal{H}_\infty$ performance measure.

Keywords

Computer control; $\mathcal{H}_\infty$ discretization; Robust control; Sampled-data systems

Introduction

Robust control deals mainly with controller design against uncertainties in system modeling and disturbances. The central tool used is $\mathcal{H}_\infty$ optimization.

In continuous time, consider the standard setup in Fig. 1, where G is the generalized plant and K is the controller; G has two inputs (w, the exogenous input, and u, the control input) and two outputs (z, the output to be controlled, and y, the measured output); K processes y to generate u. The $\mathcal{H}_\infty$-optimal control problem is to design K to stabilize G and minimize the $\mathcal{H}_\infty$ norm of the closed-loop system in Fig. 1 from w to z, denoted T_{zw}. When both G and K are continuous-time, linear time-invariant (LTI), the $\mathcal{H}_\infty$ norm, $\|T_{zw}\|$, relates to the frequency response matrix $\widehat{T}_{zw}(j\omega)$ as follows:

$$\|T_{zw}\| = \sup_\omega \bar{\sigma}\left[\widehat{T}_{zw}(j\omega)\right],$$

where $\bar{\sigma}$ indicates the maximum singular value. This $\mathcal{H}_\infty$-optimal control problem in the LTI case is solvable by many techniques, e.g., Riccati equations and linear matrix inequalities – see robust control textbooks by Zhou et al. (1996) and Dullerud and Paganini (2000).

Sampled-Data Control

When controllers are implemented by digital computers, periodic samplers and zero-order holds are used to model analog-to-digital and digital-to-analog conversion. Replacing K in Fig. 1 by sampler S (with period h), discrete-time controller K_d, and zero-order hold H (synchronized with S), we obtain a sampled-data
**Sampled-Data H-Infinity Optimization, Fig. 1**
Standard control setup in continuous time
Sampled-Data H-Infinity Optimization, Fig. 2
Sampled-data control setup

Sampled-Data H-Infinity Optimization, Fig. 3 The
equivalent discrete-time system

control system shown in Fig. 2; here, S converts y into a discrete-time sequence ψ; K_d, a real-time algorithm in the computer, inputs ψ and computes another sequence υ, which is converted by H into u.

There are in general three approaches to design a digital controller K_d: design a continuous-time controller K and then implement digitally via approximation, discretize the plant and then design K_d in discrete time, and finally, design K_d directly based on continuous-time performance specifications (Chen and Francis 1995). The last approach is followed in the $\mathcal{H}_\infty$ optimization framework.

Sampled-Data $\mathcal{H}_\infty$ Discretization

The sampled-data $\mathcal{H}_\infty$ control problem is to design K_d *directly* to stabilize G in Fig. 2 and minimize $\|T_{zw}\|$. Notice that even if G is LTI in continuous time and K_d is LTI in discrete time, the closed-loop system T_{zw} is no longer LTI, due to the presence of S and H in the control loop;

in this case, the $\mathcal{H}_\infty$ norm is interpreted as the $\mathcal{L}_2$-induced norm:

$$\|T_{zw}\| = \sup\{\|z\|_2 : \|w\|_2 = 1\};$$

here, $\|\cdot\|_2$ represents the $\mathcal{L}_2$ norm on signals.

The sampled-data $\mathcal{H}_\infty$ control problem has been shown to be equivalent to a purely discrete-time $\mathcal{H}_\infty$ control problem (Kabamba and Hara 1993; Bamieh and Pearson 1992; Toivonen 1992); the process is known as sampled-data $\mathcal{H}_\infty$ discretization: for $\gamma > 0$, construct an LTI discrete-time system $G_{eq,d}$ connected to K_d as in Fig. 3; the two systems, T_{zw} in Fig. 2 and $T_{\zeta\omega} : \omega \mapsto \zeta$ in Fig. 3, are *equivalent* in that $\|T_{zw}\| < \gamma$ if $\|T_{\zeta\omega}\| < \gamma$, where the latter norm is ℓ_2-induced, and since $T_{\zeta\omega}$ is LTI in discrete time, it equals the $\mathcal{H}_\infty$ norm of the corresponding transfer function $\widehat{T}_{\zeta\omega}(z)$. Thus, pure discrete-time techniques are immediately applicable.

There are several ways to present this discretization. However, the computation is quite involved and hence is not given here; interested readers can find details in the papers by Kabamba and Hara (1993), Bamieh and Pearson (1992), and Toivonen (1992), or the book by Chen and Francis (1995). Note that the $\mathcal{H}_\infty$ discretization process is not quite *exact* in the sense that $G_{eq,d}$ depends on γ (Chen and Francis 1995).

Summary and Future Directions

In sampled-data $\mathcal{H}_\infty$ optimization, the key idea is to address the hybrid nature of the problem,

considering intersample behavior in formulation; the main tool is the so-called continuous lifting (Yamamoto 1994; Bamieh and Pearson 1992), making use of periodicity of sampled-data systems.

The ideas and tools developed in sampled-data control theory are still being used in emerging areas such as hybrid systems and networked control systems. For example, in event-triggered control systems, information exchange and control updating are not time driven but are done by certain event-triggering schemes, resulting in necessarily nonlinear and time-varying closed-loop dynamics; the analysis and synthesis issues in such systems are still challenging.

Recommended Reading

The continuous-time $\mathcal{H}_\infty$ control problem and its solutions are discussed extensively in several textbooks, e.g., Zhou et al. (1996) and Dullerud and Paganini (2000). The discrete-time $\mathcal{H}_\infty$ control problem was solved via the approach of Riccati equations in Iglesias and Glover (1991). The sampled-data $\mathcal{H}_\infty$ control problem was solved simultaneously with different methods in Kabamba and Hara (1993), Bamieh and Pearson (1992), and Toivonen (1992); details of the solution discussed here can be found in the book by Chen and Francis (1995).

Abstract

For digital devices to interact with the physical world, an interface is needed that transforms the signals from analog to digital and vice versa. Ideal samplers and zero-order hold devices are incorporated to derive discrete-time models of continuous-time systems. State variable descriptions and transfer functions are used.

Keywords

Continuous-time approximations; Digital control; Discrete-time approximations; Quantization; Reconstruction; Sampled-data systems; Sampling

Introduction

Sampled-data systems are discrete-time models of continuous-time processes useful in the digital

S

control of continuous-time systems. A digital controller cannot communicate directly with a continuous system and an interface is needed.

Consider a continuous-time system having $u(t)$ as its input and $y(t)$ as its output.

A/D Converter: The continuous-time signal $y(t)$ is converted into a discrete-time signal $\{\bar{y}(k)\}$, $k \geq 0$, $k \in \mathbb{Z}$, which is a sequence of values $\{\bar{y}(0), \bar{y}(1), \cdots\}$ determined by the relation

$$\bar{y}(k) = y(t_k). \tag{1}$$

This is the ideal A/D (analog to digital) converter that samples $y(t)$ at times $t_0, t_1, t_2 \cdots$ producing the sequence $\{y(t_0), y(t_1), \cdots\}$ also denoted as $\{y(t_k)\}$.

D/A Converter: The D/A (digital to analog) converter receives as its input a sequence $\{\bar{u}(k)\}$, $k = 0, 1, 2, \cdots$ and outputs a (piecewise) continuous-time signal $u(t)$ determined by

$$u(t) = \bar{u}(k), \ \ t_k \leq t < t_{k+1}, \ k = 0, 1, 2, \cdots. \tag{2}$$

That is, this D/A converter keeps the value of $u(t)$ constant at the last value of the sequence entered, until a new value comes in. Such a device is called a zero-order hold (ZOH) device.

Higher-Order Hold

The ZOH device described above implements a particular procedure of *data reconstruction or extrapolation*. The general problem is as follows:

Given a sequence of real numbers $\{\bar{f}(k)\}$, $k = k_0, k_0 + 1, \cdots$ derive $f(t)$, $t \geq t_0$ so that

$$f(t_k) = \bar{f}(k), \ \ k = k_0, k_0 + 1, \cdots$$

Clearly, there is a lot of flexibility in assigning values to $f(t)$ in between the samples $\bar{f}(k)$; in other words there is a lot of flexibility in assigning the *intersample behavior* in $f(t)$.

A way to approach the problem is to start by writing a power series expansion of $f(t)$ for t, $t_k \leq t < t_{k+1}$, namely,

$$f(t) = f(t_k) + f^{(1)}(t_k)(t - t_k) + \frac{f^{(2)}(t_k)}{2!}$$
$$(t - t_k)^2 + \cdots$$

where $f^{(n)}(t_k) = \frac{d^{(n)} f(t)}{dt^n}|_{t=t_k}$, that is, the nth order derivative of $f(t)$ evaluated at $t = t_k$ (assuming that the derivatives exist).

Now if the function $f(t)$ is approximated in the interval $t_k \leq t < t_{k+1}$ by the constant value $f(t_k)$ taken to be equal to $\bar{f}(k)$, then

$$f(t) = f(t_k) \quad (= \bar{f}(k)), \ t_k \leq t < t_{k+1}$$

which is exactly the relation implemented by a ZOH. Note that here the zero-order derivative of the power series is used which leads to an approximation by a constant which is a zero-degree polynomial.

It is clear that more than the first term in the power series can be taken to approximate $f(t)$. If, for example, the first two terms are taken, then

$$f(t) = f(t_k) + f^{(1)}(t_k)(t - t_k)$$
$$= f(t_k) + \frac{f(t_k) - f(t_{k-1})}{t_k - t_{k-1}}(t - t_k)$$
$$= \bar{f}(k) + \frac{\bar{f}(k) - \bar{f}(k-1)}{t_k - t_{k-1}}(t - t_k)$$

for $t_k \leq t < t_{k+1}$, where an approximation for the derivative $f^{(1)}(t)$ has been used. The approximation between t_k and t_{k+1} is a ramp with slope determined by $f(t_k) = \bar{f}(k)$ and the previous value $f(t_{k-1}) = \bar{f}(k-1)$. Here the first-order derivative of the power series is used which leads to an approximation by a first-degree polynomial. A device that implements such approximation is called a *first-order hold (FOH)*. Similarly, we can define a *second-order hold*. Note that the formula of the above FOH is derived if we decide to use a first-degree polynomial to approximate $f(t)$ on $t_k \leq t < t_{k+1}$ and then enforce $f(t_k) = \bar{f}(k)$ and $f(t_{k-1}) = \bar{f}(k-1)$. This approach is known as *polynomial interpolation*.

Obtaining a continuous (or piecewise continuous) function from given discrete values may be seen as a *continualization procedure*. Contrast

this with the *discretization procedure* introduced by sampling earlier in this section.
The continuous-time system with input $u(t)$ and output $y(t)$ together with the interface A/D and D/A converters can be seen as a system that receives a sequence of values $\{\bar{u}(k)\}$ as its input and produces a sequence of output values $\{\bar{y}(k)\}$. A digital controller can receive the system output $\{\bar{y}(k)\}$ as input and produce a $\{\bar{u}(k)\}$.

Quantization: The sampled output $\bar{y}(k) \in \mathbb{R}$ and it can take on an infinite number of values. In a digital device, however, a variable can take on only a finite number of values – this is because of the finite wordlength that is of the finite number of bits in the registers. So for $\{\bar{y}(k)\}$ to be used by a digital controller, an additional step is needed, that is, $\bar{y}(k)$ needs to be quantized. Under quantization, for example, values 2.315, 2.308, 2.3 with a 0.1 quantization step are all represented as 2.3. Quantization is an approximation and for short wordlengths, fewer number of levels, may lead to significant errors. Here we do not consider quantization.

Discrete-Time Models

Let a linear, continuous-time, time-invariant system be described by

$$\begin{aligned} \dot{x}(t) &= Ax(t) + Bu(t), \\ y(t) &= Cx(t) + Du(t). \end{aligned} \tag{3}$$

If we consider some initial time t_k, its state response for $t \geq t_k$ is

$$x(t) = e^{A(t-t_k)}x(t_k) + \int_{t_k}^{t} e^{A(t-\tau)}Bu(\tau)d\tau. \tag{4}$$

In view of (2), in a ZOH the input $u(t)$ will remain constant and equal to $u(t_k) (= \bar{u}(k))$ for a time period $t_{k+1} - t_k$. So

$$x(t) = e^{A(t-t_k)}\bar{x}(k) + \left[\int_{t_k}^{t} e^{A(t-\tau)}Bd\tau \right]\bar{u}(k), \tag{5}$$

where $\bar{x}(k) = x(t_k)$, $\bar{u}(k) = u(t_k)$. For $t = t_{k+1}$, (5) becomes

$$\bar{x}(k+1) = \bar{A}(k)\bar{x}(k) + \bar{B}(k)\bar{u}(k) \tag{6}$$

where $\bar{A}(k) \triangleq e^{A(t_{k+1}-t_k)}$ and $\bar{B}(k) \triangleq \int_{t_k}^{t_{k+1}} e^{A(t_{k+1}-\tau)}Bd\tau$.

Consider now the output $y(t)$ and assume that it is sampled at times t_k' that do not necessarily coincide with the instants t_k at which the input is adjusted ($t_k \leq t_k' < t_{k+1}$). Then if $\bar{y}(k) \triangleq y(t_k')$,

$$\bar{y}(k) = \bar{C}(k)\bar{x}(k) + \bar{D}(k)\bar{u}(k), \tag{7}$$

where

$$\bar{C}(k) = Ce^{A(t_k'-t_k)}$$
$$\bar{D}(k) = C\left[\int_{t_k}^{t_k'} e^{A(t_k'-\tau)}d\tau \right]B + D.$$

In the case when all $k = 0, 1, 2, \cdots$, $t_k' = t_k$ and $t_{k+1} - t_k = T$ a constant period, called the *sampling period*. Then the sampled-data system is given by

$$\begin{aligned} \bar{x}(k+1) &= \bar{A}\bar{x}(k) + \bar{B}\bar{u}(k) \\ \bar{y}(k) &= \bar{C}\bar{x}(k) + \bar{D}\bar{u}(k) \end{aligned} \tag{8}$$

where

$$\bar{A} = e^{AT}, \quad \bar{B} = \left[\int_0^T e^{A\tau}d\tau \right]B,$$
$$\bar{C} = C, \quad \bar{D} = D.$$

The intersample behavior of the continuous system can be determined using (5).

Example 1 Let the continuous-time system be given by (3) where

$$A = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}, B = \begin{bmatrix} 0 \\ 1 \end{bmatrix}, C = [1 \quad 0], D = 0,$$

and let T denote the sampling period. The transfer function of the continuous-time system is $\hat{H}(s) = C(sI - A)^{-1}B = 1/s^2$, the double integrator. The discrete-time state-space representation of the system, which represents the continuous-time system preceded by a zero-order hold (D/A converter) and followed by a sampler [an (ideal) A/D converter], both sampling synchronously at a rate of 1/T, is given by $\bar{x}(k+1) = \bar{A}\bar{x}(k) + \bar{B}\bar{u}(k)$, $\bar{y}(k) = \bar{C}x(k)$, where

$$\bar{A} = e^{AT} = \sum_{j=1}^{\infty}(T^j/j!)A^j = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} +$$

$$\begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}T = \begin{bmatrix} 1 & T \\ 0 & 1 \end{bmatrix},$$

$$\bar{B} = \left(\int_0^T e^{A\tau}d\tau\right)B$$

$$= \left(\int_0^T \begin{bmatrix} 1 & \tau \\ 0 & 1 \end{bmatrix}d\tau\right)\begin{bmatrix} 0 \\ 1 \end{bmatrix}$$

$$= \begin{bmatrix} T & T^2/2 \\ 0 & T \end{bmatrix}\begin{bmatrix} 0 \\ 1 \end{bmatrix} = \begin{bmatrix} T^2/2 \\ T \end{bmatrix},$$

$$\bar{C} = C = [1 \quad 0].$$

The transfer function (relating $\bar{y}$ to $\bar{u}$) is given by

$$\hat{H}(z) = \bar{C}(zI - \bar{A})^{-1}\bar{B}$$

$$= [1\ 0]\begin{bmatrix} z-1 & -T \\ 0 & z-1 \end{bmatrix}^{-1}\begin{bmatrix} T^2/2 \\ T \end{bmatrix}$$

$$= [1\ 0]\begin{bmatrix} 1/(z-1) & T/(z-1)^2 \\ 0 & 1/(z-1) \end{bmatrix}$$

$$\begin{bmatrix} T^2/2 \\ T \end{bmatrix}$$

$$= \frac{T^2}{2}\frac{(z+1)}{(z-1)^2}.$$

If we focus on single-input, single-output systems and consider ideal sampler A/D and ZOH D/A, then given the transfer function $G(s)$ of the continuous system, there is a direct formula to determine the transfer function of its discrete approximation $H(z)$, namely,

$$H(z) = (1 - z^{-1})Z\{G(s)/s\}. \qquad (9)$$

Here $Z\{G(s)/s\}$ means that first the inverse Laplace transform of $G(s)/s$ is taken to obtain $f(t) \triangleq [\mathcal{L}^{-1}(G(s)/s)]$. The function $f(t)$ is then sampled to obtain $f(kT), k = 0, 1, 2, \cdots$ and the z-transform of $f(kT)$ is evaluated. To illustrate, in the above example $G(s) = \frac{1}{s^2}$, $G(s)/s = \frac{1}{s^3}$, and $f(t) = \mathcal{L}^{-1}(\frac{1}{s^3}) = \frac{1}{2}t^2$, $t \geq 0$. Then

$$H(z) = (1 - z^{-1})Z\{\frac{1}{2}(kT)^2\}$$

$$= (1 - z^{-1})\frac{T^2}{2}Z\{k^2\}$$

$$= \frac{T^2}{2}\frac{z+1}{(z-1)^3}$$

as before.

Summary

Sampled-data systems arise in the digital control of systems and include both continuous and discrete-time dynamics. Discrete-time approximations of continuous-time systems using ideal samplers and ZOH devices were derived using state variable descriptions. Extensions include quantization and lead to hybrid dynamical systems which include both continuous and discrete variable dynamics.

A variation of the approach described in this entry of deriving sampled-data systems uses the discrete-time delta operator. This approach has the advantage that as the sampling period $T \rightarrow 0$, the discrete-time model reverts to the original continuous-time model, which is not the case with the more common approach described above.

Abstract

Spacecraft control systems are described for single and distributed space systems. The attitude dynamics is formulated including flexible and sloshing phenomena, followed by a description of attitude sensors and actuators. $\mathcal{H}_\infty$ and robust controls are formulated as signal-based two degree-of-freedom control architectures. The equations are given for the relative motion dynamics between spacecraft on elliptical orbits with the generic Yamanaka-Ankersen state transition matrix. Formulations are provided for rendezvous and docking scenarios and formation flying control, maneuvers, avionics, and laser metrology systems together with the onboard autonomy needs.

Keywords

Flexible modes; Formation flying; Fractionated spacecraft; $\mathcal{H}_\infty$ control; Multivariable systems; Relative dynamics; Rendezvous and docking; Robust control; Sloshing; Spacecraft attitude control; Spacecraft position control

Introduction

This entry explains the control needs of spacecraft after they have been separated from the launch vehicle and injected onto their initial orbit.

Actuators and sensors are explained followed by the control objectives. The state-of-the-art control techniques and architectures are addressed.

Spacecraft are classically well-known physical systems that can be described by first principles. The advantage is fairly precise plant models and uncertainty characterization of physical parameters. This is well suited for a model-based control design approach.

Mission Types

From a control point of view, space missions can be split into two main categories according to which physical states need to be controlled:

Attitude Control: This is needed by any spacecraft irrespective of the mission objectives. Such missions are typically low earth orbit (LEO) missions for astronomy, observations,

and, in higher orbits, constellations for navigation and communication. Further, there are interplanetary and planetary exploration science missions. The pointing requirements vary from a few degrees to milli-arc seconds.

Relative Position Control: Within distributed space systems, this is relevant for rendezvous and docking (RVD) and formation flying (FF) missions. It leads to a 6 degree-of-freedom (DOF) control problem as the relative attitude is also needed. The former is mostly for missions to space station logistics infrastructures and the latter for scientific missions. Relative position can also be required during the final stages of controlled planetary landings. Another category is missions with ultrahigh control performance requirements, where the spacecraft platform and the science instrument need to be considered as one coupled system.

Attitude Control

Fundamentally the three attitude angles $\boldsymbol{\theta}$ and angular rates $\boldsymbol{\omega}$ need to be controlled to a certain reference. See Fig. 1 for definition.

The general rigid body dynamics expressed in a rotating frame(∗), which is mostly the case when orbiting a central body, can be expressed as

$$\mathbf{N} = \frac{d^*(\mathbf{I}\boldsymbol{\omega}^*)}{dt} + \boldsymbol{\omega} \times \mathbf{I}\boldsymbol{\omega}^* \qquad (1)$$

where $\mathbf{I}$ is the constant inertia matrix, $\boldsymbol{\omega}$ is the inertial angular velocity, and $\mathbf{N}$ is the torque acting on the spacecraft (Wie 1998).

The kinematics can be described by one of the 12 sets of Euler angles (can have singularities) or the hypercomplex quaternion vector (no singularities) (Hughes 1986).

The dynamics and kinematics equations need to be linearized and are in the general form of a coupled 12th order system. It is the fundamental model for the rigid body spacecraft control design.

Most modern spacecraft have large flexible appendices in the form of solar panels and large antennae reflectors. Fuel sloshing is a similar lightly damped oscillatory phenomena, which often needs to be taken into consideration. The incorporation of dynamic elements such as flexible panels, antennae, and sloshing fuel can be modeled by Eqs. (2) and (3) provided the overall rotation rate $\boldsymbol{\omega}$ and linear accelerations $\ddot{\mathbf{x}}$ are not too large.

$$\mathbf{M}_T \begin{bmatrix} \ddot{\mathbf{x}} \\ \dot{\boldsymbol{\omega}} \end{bmatrix} = \begin{bmatrix} \mathbf{F} \\ \mathbf{N} \end{bmatrix} - \mathbf{L}\ddot{\boldsymbol{\eta}} \qquad (2)$$

$$\ddot{\eta}_k + 2\zeta_k \Omega_k \dot{\eta}_k + \Omega_k^2 \eta_k = -\frac{1}{m_k}\mathbf{L}^{\mathrm{T}} \begin{bmatrix} \ddot{\mathbf{x}} \\ \dot{\boldsymbol{\omega}} \end{bmatrix} \qquad (3)$$

Satellite Control, Fig. 1
Spacecraft body (*black*) and reference (*red*) frames. The frames coincide for $\boldsymbol{\theta} = \mathbf{0}$
where

$\mathbf{M}_T$	: rigid body mass/inertia matrix
$\ddot{\mathbf{x}}, \dot{\boldsymbol{\omega}}$	: linear and angular acceleration
$\mathbf{F}, \mathbf{N}$	: forces and torques on the spacecraft
η_k	: the kth flexible state
ζ_k	: the kth flexible damping factor
Ω_k	: the kth flexible eigen frequency
m_k	: the kth modal mass (normalized to 1)
$\mathbf{L}$	: participation matrix of the kth mode

For attitude only the second row of Eq. (2) is needed, but translation is included here for the sake of completeness and later use.

The sensors utilized are typically gyroscopes for measuring the inertial angular rate, sun sensors to measure orientation at low accuracy, and star trackers for high-precision angular attitude measurements. All of those sensors are linear in their normal operational range and it suffices to use bias noise models for synthesis. Gyros do need a drift estimation and compensation to function properly over longer time. All sensors utilize redundancy for providing measurements around all three axes as well as providing fault tolerance. Some scientific observatory spacecraft use their telescopes for attitude measurements in order to obtain the required precision beyond the capability of star trackers.

The actuators producing pure torques are magnetic torquers, reaction wheels, and control momentum gyros. The last can produce large torques used for rapid slew maneuvers with little power. The last two types have nonlinear issues around low to zero speed due to friction issues. They accumulate angular momentum from asymmetric disturbances. This leads to a need for thrusters for angular momentum off-loading. Thrusters are also used to control the attitude directly on many spacecraft. They are mostly of on-off type, though continuous ones exist, and will need to be pulse width modulated (PWM) to obtain quasi-linear behavior. The nonlinear on-off nature needs to be taken into account for the control closed loop analysis. It is done by use of the negative inverse describing function (Ogata 1970) for stability analysis and nonlinear modeling for verification simulations in the time domain. For larger numbers of thrusters, an optimization-based selection algorithm is applied to the controller output.

Before using the plant model in Eq. (2) for a flexible spacecraft, a simpler multivariable model of a rigid spacecraft is used as in Eq. (4):

$$\dot{\mathbf{x}} = \begin{bmatrix} \mathbf{0} & \mathbf{B}_k \\ \mathbf{0} & \mathbf{A}_d \end{bmatrix} \mathbf{x} + \begin{bmatrix} \mathbf{0} \\ \mathbf{B}_d \end{bmatrix} \mathbf{N} \qquad (4)$$

where $\mathbf{x} = [\theta_x, \theta_y, \theta_z, \omega_x, \omega_y, \omega_z]^{\mathrm{T}}$, $\mathbf{B}_k$ is identity, $\mathbf{B}_d = \mathbf{I}^{-1}$, and $\mathbf{A}_d$ is the general Jacobian for the dynamics having a real right half-plane (RHP) pole. See Ankersen (2011). The model describes the angular deviation from some reference frame, whose orientation can be arbitrary. It uses the Euler (3, 2, 1) rotation in the kinematics.

The state of the art of attitude control is today mostly based on $\mathcal{H}_\infty$ type of robust controllers with synthesis performed in the frequency domain. Requirements are often specified in the time domain, but formal methods exist to transform them into frequency domain weighting functions (ESA Handbook 2011) enhancing both synthesis and analysis. System uncertainties can be formulated as structured linear fractional transformations (LFT) with a general control configuration as illustrated in Fig. 2.

Commonly the $\mathcal{H}_\infty$ controller $\mathbf{K}$ is designed, and the lower loop in Fig. 2 is closed via a lower LFT such that $\mathbf{N} = F_l(\mathbf{P}, \mathbf{K})$ and robust stability (RS) and robust performance (RP) analysis is performed on the $\mathbf{N}, \boldsymbol{\Delta}$ system (Skogestad and Postlethwaite 1996).
Satellite Control, Fig. 2 Robust control formulation, where $\boldsymbol{\Delta}$ is the structured uncertainty, $\mathbf{K}$ is the controller, $\mathbf{P}$ the partitioned formulation of the plant with weights, and $\mathbf{w}$ and $\mathbf{z}$ are exogenous inputs and outputs, respectively

On high performance pointing spacecraft, active vibration suppression of, e.g., cryocoolers is needed. The implementation of control design and recursive system identification can achieve significantly better attenuation compared to classical passive isolation techniques.

Lately optimization-based codesign of structures and control has been performed successfully. A joint performance function is formulated (mass, stiffness, pointing, fuel, etc.) and an optimization is performed (differential evolution algorithm) iterating on control design and finite element models (FEM). A μ-synthesis controller is synthesized, the pointing performance is fulfilled, and 15–20 % mass saving is obtained on the flexible structures. The entire process is fully automated (Falcoz et al. 2013).

Relative Position Control

For all distributed space systems, relative dynamics is important. Rendezvous and formation flying missions need tracking or maintenance of the desired relative separation, orientation, and position between or among the spacecraft. This is common and independent of the mission type and will be described in general terms ahead of the specific RVD and FF missions.

The general relative position dynamics between centers of mass (COMs) is in Eq. (5), where it is observed that the in-plane motion (x, z) is decoupled from the out-of-plane motion (y).

$$\ddot{x} - \omega^2 x - 2\omega\dot{z} - \dot{\omega}z + k\omega^{\frac{3}{2}}x = \frac{1}{m_c}F_x$$
$$\ddot{y} + k\omega^{\frac{3}{2}}y = \frac{1}{m_c}F_y \quad (5)$$
$$\ddot{z} - \omega^2 z + 2\omega\dot{x} + \dot{\omega}x - 2k\omega^{\frac{3}{2}}z = \frac{1}{m_c}F_z$$

where $\omega = \omega(t)$ is the orbital angular rate, m_c is the chaser mass, F_{xyz} is the force on the chaser, and k is a constant determined by the orbit and is valid for any Keplerian orbit with eccentricity $\varepsilon < 1$.

The Yamanaka-Ankersen equations (Yamanaka and Ankersen 2002) provide the generalized homogeneous solution in the form of the transition matrix $\boldsymbol{\Phi}$, where the solution can be written as

$$\mathbf{x}(t) = \boldsymbol{\Lambda}^{-1}(\nu)\boldsymbol{\Phi}(\nu)\boldsymbol{\Phi}_0^{-1}(\nu_0)\boldsymbol{\Lambda}(\nu_0)\mathbf{x}(t_0) \quad (6)$$

where ν is the orbital true anomaly and Λ are transformation matrices to and from the time domain. The elements of $\boldsymbol{\Phi}$ in Eq. (6) are detailed in (Ankersen 2011), where relevant particular solutions are also to be found. Equation (6) reduces to the well-known Clohessy-Wiltshire equations for circular orbits ($\varepsilon = 0$) (Clohessy and Wiltshire 1960). Equation (6) is used for feedforward control and trajectory propagation in the guidance function. During the final approach (see Fig. 3), a model accounting for the docking port-to-port relative position and the couplings from the relative attitude to the position is utilized and formulated in Eqs. (7) and (8) (Ankersen 2011):

$$\dot{\mathbf{x}} = \begin{bmatrix} \mathbf{A}_p & \mathbf{0} \\ \mathbf{0} & \mathbf{A}_c \end{bmatrix}\mathbf{x} + \begin{bmatrix} \mathbf{B}_p & \mathbf{0} \\ \mathbf{0} & \mathbf{B}_c \end{bmatrix}\mathbf{u} \quad (7)$$

$$\mathbf{y} = \begin{bmatrix} \mathbf{I} & \mathbf{0} & \mathbf{B}_{dc_1} & \mathbf{0} \\ \mathbf{0} & \mathbf{I} & \mathbf{0} & \mathbf{B}_{dc_2} \\ \mathbf{0} & \mathbf{0} & \mathbf{I} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{I} \end{bmatrix}\mathbf{x} \quad (8)$$

where $\mathbf{x} = [\mathbf{x}_p, \dot{\mathbf{x}}_p, \boldsymbol{\theta}_c, \boldsymbol{\omega}_c]^{\mathrm{T}}$, $\mathbf{y} = [\mathbf{x}_{pp}, \dot{\mathbf{x}}_{pp}, \boldsymbol{\theta}_c, \boldsymbol{\omega}_c]^{\mathrm{T}}$, index p refers to COM positions, index c to chaser attitude, index pp to port-to-port position, and $\mathbf{B}_{dc_1}, \mathbf{B}_{dc_2}$ are the coupling matrices of the docking port.

A relative motion scenario for a typical RVD mission looks like in Fig. 4. During the final approach (<300 m range), the chaser relative attitude and relative position are controlled. During the other phases, the chaser attitude is Earth pointing and the relative position is controlled at the station-keeping (SK) points, $s_0, \cdots, s_4$ in Fig. 4. The trajectories are typically open loop feedforward controlled (often with midcourse corrections).

The avionics sensors for the attitude control part are generally similar to those described earlier under attitude control in connection with Fig. 1. Active laser CCD type of sensors

Satellite Control, Fig. 3

Satellite Control, Fig. 4 This figure shows the phases of typical relative motion approach. The *shaded area* is a keep-out zone (KOZ) defined for safety reasons. V-bar is the x-axis and R-bar is the z-axis

is used to measure the relative position (range and line-of-sight (LOS) angles) and at short range (<50 m) the relative attitude. They require a target pattern to provide precise measurements at short range. Accelerometers are used, particularly for pulsed maneuvers. The next generation of RVD GNC systems, test flown, will utilize Lidar, infrared cameras, and visual cameras in combination with advanced image processing providing RVD capabilities with both cooperative and passive target spacecraft.

The actuators are mostly thrusters arranged to achieve controllability for all the 6DOF maneuvers needed. Based upon the controller output, the active thrusters are selected by means of some

type of fuel optimization algorithm. The selected thrusters are then pulse width modulated (PWM) within the sampling time.

The controllers are frequently of multivariable $\mathcal{H}_\infty$ type. They are similar to what is described in connection with Fig. 2. Flexible modes and in particular sloshing need to be taken into account using Eq. (2). Sloshing pendulum models are used during boost maneuvers and spring mass damper models during other modes. The couplings between relative attitude and relative position in Eq. (8) can be analytically decoupled setting the matrix $\mathbf{C}$ to identity and premultiplying with a decoupling matrix $\mathbf{V}_d$, such that

$$\mathbf{V}_d \mathbf{C} = \mathbf{I} \Leftrightarrow \mathbf{V}_d = \mathbf{C}^{-1} \qquad (9)$$

Satellite Control, Fig. 5
Principal structure of the 2
degree-of-freedom
controller
and by the inversion theorem for partitioned matrices the upper right partition just changes sign. The designed controller then needs to be premultiplied by $\mathbf{V}_d^{-1}$, which facilitates a simpler control design maintaining the 6DOF performance after 2 times 3DOF synthesis.

A 2 degree-of-freedom control architecture as in Fig. 5 is beneficial since much of the performance is achieved by controller $\mathbf{K}_1$. The structure of the synthesis formulation is a signal-based model-reference configuration for the $\mathcal{H}_\infty$ control rather than the more classical mixed sensitivity type. It has proven to have higher robustness and performance for this type of applications. As an example, consider a controller that has to follow a sawtooth motion of the docking port of the International Space Station (ISS) with an amplitude of 0.4 m and reversal times of 8 s. The signal-based model-reference controller manages to track such a motion with errors less than 0.01 m compared to the best operational performance of 0.08 m.

Formation flying usually includes more than two spacecraft with the need to be controlled relative to each other. The objective of FF is to form an instrument in space, not possible with fixed structures, like a synthetic aperture or an interferometer of large size.

The performance needs are high and require innovative high-precision ($<1\,\mu$m) metrology sensors. They are based on divergent laser beams for the coarse part to be able to transit from lower to higher accuracy. The fine metrology uses a laser beam and internal interferometers to reach the μm domain. Actuators are in the range of μN thrust, which can be achieved with either cold gas or electrical propulsion thrusters.

The maneuvers realized by entire formations are rotation, resizing, and slew while maintaining the formation in most cases (Alfriend et al. 2010).

Formation flying missions with the highest performance requirements have optical payloads, which need to have internal control loops at component level. To reach the performance required for applications such as optical interferometry, the formation and payload must be considered as one system. The synthesis of a multivariable controller then handles all the cross couplings in the system needed to reach performance. Beyond flexible modes, such systems might also have a need for active vibration damping for systems using cryocoolers.

The GNC architecture is often centralized for nominal science operational modes. For the formation deployment and contingency situations, a decentralized control architecture is needed. This leads to a dual architecture GNC system in general for formation flying systems. The onboard autonomy needs to be fairly high in order to cope with the contingencies in the formation without ground intervention.

Finally there is an emerging concept of fractionated spacecraft. There, a formation consists of a large number of small simple vehicles maneuvering relative to each other fully autonomously based upon the nearest neighbor knowledge and not necessarily information about the entire formation (Cornford 2012).

Summary and Future Directions

The control of spacecraft has been described for pure attitude control needs and for spacecraft performing relative proximity maneuvers like rendezvous and formation flying. The focus has been on sensors, actuators, dynamics, and the robust control methods applied today.

The further development direction of the field is expected to be increased on board autonomy with replanning capabilities and fault-tolerant

GNC designs. Model predictive control (MPC) will enter in particular on the guidance functions. More integrated GNC system-level designs, of multidisciplinary nature, are expected.

Scheduling of Batch Plants

John M. Wassick
The Dow Chemical Company, Midland, MI, USA

Abstract

For manufacturers operating batch plants, production scheduling is a critical and challenging problem. A thorough understanding of the problem and the variety of solutions approaches is needed to achieve a successful application. This entry will present a brief overview of batch operations and the state of the art of batch plant scheduling for nonexperts in the field.

Keywords

Dispatching rules; Optimization; Process networks; Production sequencing; Product wheel

S

Introduction

Batch plants, manufacturing operations composed of unit operations that operate in batch mode, are the primary manufacturing operations for the production of high margin products such as pharmaceuticals, specialty chemicals, and advanced materials. The scheduling of the sequence of operations over time has a significant impact on the overall performance of a batch plant (White 1989). The economic importance of batch plants, and the importance of scheduling for batch plants, has spawned a large body of

research on the topic and a variety of commercial offerings.

The Nature of Batch Plants

In batch operations, the material transformation takes place in stages and the operation of each stage occurs over a specified time while the material remains in a particular unit operation performing that stage of production. (A familiar batch operation is baking a cake. Ingredients and their amounts, specified by a recipe, are combined and then subjected to a constant temperature over specified period of time to produce a cake.) A batch plant may have parallel units for some stages. Other stages may be operated in a continuous flow mode with a storage unit feeding the stage and another storage unit receiving the stage output. The path through the unit operations may be product dependent. Batch plants have highly diverse operational characteristics.

There are two broad categories of batch processes: (1) sequential where a batch moves from one stage to another without losing its identity and (2) networked where batches can be combined or split to feed downstream units (Mendez et al. 2006). Sequential processes can be further classified as single stage, multi-stage, or multipurpose.

The nature of a batch process and the different process structures can be explored by referring to the process depicted in Fig. 1 (Chu et al. 2013). As drawn, this batch plant operates as a multi-stage sequential process where a batch starts in raw material preparation stage (selected raw materials are loaded and then blended for a specified time), moves to the reaction stage with two parallel units (prepared raw materials plus additives react at a constant temperature for a specified period of time), moves to the finishing stage (intermediate product is subjected to a vacuum for a specified period of time to remove volatile by-products), and finally is processed in the drumming stage (finished product is packaged in drums). If finished product storage tanks were placed between finishing and drumming to allow the drumming stage to be scheduled independently of the first three stages, then the drumming operation would represent a single stage sequential process. If we further assume that for some finished products Reactor 1 produces a batch of precursor for Reactor 2 and that some products produced in the reactors bypass the finishing stage and go directly to drumming, then the underlying plant would be a multi-purpose sequential process. Finally, if intermediate storage tanks exist for storing multiple batches of the precursors produced by Reactor 1 and the contents of the tanks are drawn off to produce multiple, subsequent batches in both reactors then the underlying plant is a networked process.

Besides the general structure of a batch plant, the specific processing requirements, resources needs, and process constraints have significant impact on the complexity of the scheduling problem. One important aspect is limited resources that are shared between different operations. The availability and capacity of shared resources place a severe constraint on the timing of competing operations. Another significant factor is intermediate storage between
Scheduling of Batch Plants, Fig. 1 Example batch plant (*Solid lines* represent material flows from limited inventory. *Dashed lines* represent material flow from unlimited inventory)

stages and the inventory policies that are enforced. Like shared resources, intermediate storage places hard constraints on the timing of upstream and downstream stages, especially when no storage is available. A third important constraint on scheduling is product transition policies that dictate what operations need to be performed to move from one product to another in a given stage. Such operations, sometimes called setups, might involve cleaning, or producing buffer batches to isolate the chemistry of one product from another. These operations involve costs and subtract from the productive use of the equipment so they have significant impact on the sequencing of products through the plant.

Production Scheduling of Batch Plants

Production scheduling in a batch plant involves three fundamental decisions: (1) determining the size of each batch in each stage, (2) assigning a batch to a processing unit in each stage, and (3) determining the sequence and timing of processing on each unit. These decisions are well illustrated by a graphical planning board or Gantt chart as shown in Fig. 2 (Chu et al. 2013). Personnel charged with creating and managing production schedules often rely on such a graphical tool to construct, analyze and report the schedule. Generally production schedules are determined using the information listed in Table 1.

The scope of the scheduling decisions is defined by the level of process detail considered in the scheduling problem. This idea can be examined by referring to Figs. 1 and 2. Such a Gantt chart could apply to a batch plant with four stages of production: raw material preparation, reaction, finishing, and drumming, with two parallel reactors in the reaction stage. If dedicated finished product storage exists with large enough capacity to cover the process lead time then one schedule could be confined to the first three stages of production and a different schedule applied to the drumming stage. The scope of the scheduling problem could be further reduced if raw material
Scheduling of Batch Plants, Fig. 2 Gantt chart of a production schedule

Scheduling of Batch Plants, Table 1 Information generally used to construct a production schedule

Scheduling information	Examples
Detailed production recipes	Batch times, processing rates, unit ratios, sequence dependencies
Equipment data	Capacities, availabilities, product suitability
Facility information	Shared resource availability and capacities, storage capacities
Production costs	Raw materials, utilities, setups, cleanings, manpower
Production targets	Inventory replenishments, customer orders with due dates
Current process status	Current inventories, operations in progress, schedule items fixed in future time

preparation only takes place just in time to load a reactor rather than execute as soon as possible. In this situation, the time for raw material preparation could be added to the reactor batch time and the schedule would involve only the reactors and the finishing system with the raw material unit or units schedule implied by the reactor schedule. At a higher level still, the first three stages of production could be considered a production train and scheduling could then be reduced to planning campaigns of batches for each product over time with the detailed synchronization of the individual stages left to operations personnel. Obviously with each level of abstraction some efficiency in the schedule is lost and subsequently the opportunity to increase throughput of the plant.

In most batch plants a person with a title such as "production scheduler" is charged with the scheduling decisions. In general, the production scheduler is responsible for delivering a production schedule that meets customer orders on time and maintains finished product inventory while dealing with rush orders, late deliveries, equipment breakdowns and other contingencies. Generally schedulers develop and publish a schedule to manufacturing on a regular basis (e.g., every 2 days, once a week, etc.) and then monitor ongoing circumstances (e.g., actual production vs. plan, new demand, etc.) to determine if minor adjustments to the schedule are needed or if a complete new schedule needs to be published. The construction of a schedule can be an iterative process involving negotiations with manufacturing, supply chain, sales, maintenance and logistics. The tools available to the production scheduler can have a significant impact on the quality of schedules they produce.

It is evident from the description above that production scheduling of batch plants is really carried out as an exercise in rescheduling in response to disturbances identified through feedback from the process and market. Under these circumstances production scheduling serves as a form of high level feedback control of the process. In this regard the manipulated variables are the production amounts for each product and the controlled variables are the inventory levels and customer service levels for each product. A scheduling problem can be converted to a state-space formulation and compared to model predictive control (Subramanian et al. 2012).

Solution Approaches

The solution approaches applied to scheduling batch plants cover a wide spectrum of sophistication. A very simple form is nothing more than a sequence of batches maintained on a white board in the plant control room. A level above this would be the use of custom spreadsheets for arranging batches chronologically and computing finished product inventory. Another step up is the use of a manually manipulated Gantt chart as illustrated in Fig. 2, possibly pre-populated by an automated planning application that determines the volume to be produced across the units of production while leaving the detailed sequencing and timing decisions to the production scheduler. The highest level of sophistication involves an automatically generated schedule with the application retrieving all the necessary data from the appropriate business databases and plant control system.
Regardless of the level of sophistication, all solution approaches rely on two fundamental components for developing a schedule. One is the modeling paradigm used to represent the physical system in a more abstract way. The primary components are: material balances in terms of batches or units of measure (e.g., pounds), and timing information as either precedence-based describing the order of operations or time grid-based describing the instant at which any operation takes place. Time can either be described by a continuous representation or divided into discrete increments. Within these two aspects of the modeling framework, significant freedom exists to describe the scheduling problem. The second fundamental component is the solution method used to generate the schedule. Each method has its strengths; therefore solutions combining methods are also used. The essential problem is to produce the information needed to draw the Gantt chart in Fig. 2 given the information in Table 1.

Product Wheel

While the primary objective of production scheduling is to meet customer orders while managing finished product inventory, other operational issues need to be managed, such as minimizing product transition costs, minimizing variability in manufacturing operations, keeping the scheduling process simple, and balancing the tradeoff between production lead times, inventory, and transition losses. The product wheel is a practical approach widely used in industry to address these competing issues. A product wheel is a regular repeating sequence of products made on a specific unit operation or an entire production process. A product wheel is typically depicted as a pie chart as shown in Fig. 3. Segments of the pie, called spokes of the wheel, represent a production campaign of a particular product. The size of the spoke represents the length of the campaign relative to the overall duration, or cycle time, of the wheel.

A product wheel has specific design parameters to address various operations objectives. The sequences is fixed and optimized for minimum transition costs. The overall cycle time is fixed and optimized to balance lead time and inventory costs. The campaign size or spokes for each product are sized to match average demand for each product. The fixed pattern of the product wheel provides manufacturing with a predictable operational rhythm and the production scheduler with a very structured decision framework. Refer to King and King (2013) for a complete treatment of product wheels.

In practice, the duration of a campaign for a given product will vary from cycle to cycle as it will be sized to replenish any inventory consumed in the previous cycle. Low volume products may not be made on every cycle, although they will have a fixed location in the sequence. This same approach applies to make-to-order products that are not inventoried but produced to fill specific orders. Thus, in some cases a product wheel may be composed of several different but repeating cycles.

Dispatching Rules Used in Discrete Manufacturing

Batch processes are closely related to discrete manufacturing. Batches processed on a unit are analogous to jobs processed on a machine. Much of the literature on machine scheduling has focused on the analysis of the specifics encountered in general classes of problems such as single machines, parallel machines, flow shops and job shops, and developing constructive scheduling rules where a schedule is built up by adding one job at a time (Blackstone et al. 1982). Under certain circumstances these rules used for machine scheduling can be applied to scheduling batch plants. This allows one to take advantage of a great body of literature, and at times, very simple scheduling rules that have proven optimality or worst case performance limits.

Consider again the batch process referred to in Fig. 1 which has two parallel reactors. The two reactors can be modeled as a single stage process and scheduled like parallel machines using the simple *shortest processing time first* (SPT) rule if the following circumstances hold: (1) raw material preparation can be included in the batch time of reactors, (2) significant storage exists between the reactors and finishing to essentially isolate the two stages, (3) product specific batch times are identical for both reactors, (4) the number of batches of each product is given (perhaps the result of an inventory policy for make to stock products), and (5) the objective is to minimize the total completion time for all batches. The SPT rule is simply to select, whenever a reactor is free, the batch with the shortest processing time from those yet to be processed. This can be proven to produce an optimal schedule for the given conditions.

Scheduling of Batch Plants, Fig. 3 Product wheel

Another simple dispatching rule to mention is the *earliest due date first* (EDD) rule. This rule is designed for single stage processes without parallel units where each batch has an associated due date. The rule simply orders the batches in increasing order of their due dates to minimize the maximum lateness of all orders.

The conditions needed for the SPT rule or the EDD rule to produce an optimal schedule can be quite restrictive when considering batch processes, however these rules and others found in the machine scheduling literature (Baker and Trietsch 2009) can still produce a good initial schedule even in cases where optimality conditions are not satisfied. Once generated, the schedule can be improved by manual manipulation of the Gantt chart or the application of improvement heuristics.

Improvement Heuristics

Improvement heuristics try to improve the current schedule by searching for alternative solutions either in the neighborhood of the current schedule or by broadly exploring the solution space. The behavior of these algorithms is determined by tuning parameters that balance the use of the two search techniques and the underlying algorithm that performs the search. Improvement heuristics generally have the following basic procedure:

Step 1: Initialize – determine a starting schedule

Step 2: Generate alternatives – build modifications to the current schedule

Step 3: Check for improvements in modified schedule – if no improvement is found return to Step 2 otherwise proceed to Step 4

Step 4: Check for termination – terminate the algorithm if the number of iterations is exceeded or minimal improvement is obtained.

Many improvement heuristics are inspired by processes found in nature. Two of the more popular heuristics are simulated annealing which mimics the crystal formation during the cooling process of dense matter (Ryu et al. 2001) and genetic algorithms that mimic the evolution of a species over time (Löhl et al. 1988). A key aspect of improvement heuristics is the representation of the schedule in context of the algorithm used. For problems with complicated constraints this becomes a challenge. Nevertheless, when tuned

properly and used where they fit the problem, improvement heuristics can produce very good schedules quickly.

Tree Search Methods

The scheduling solutions considered so far have taken a relatively simple view of a batch process as a single stage process or a flow shop. In situations where a batch plant involves shared resources, complicated transition rules or is a process network, tree search methods are better suited because they can deal with a large number of degrees of freedom and many types of constraints. Tree search methods rely on representing alternative schedules as the final nodes in a tree where intermediate nodes represent partial solutions of the schedule. To be practical, these methods must be able to effectively search through the tree while pruning non promising branches (see Fig. 4). Three of the most popular techniques are mathematical programming, constraint programming, and beam search.

Mathematical programming solution techniques for scheduling generally convert the problem to a mixed integer linear programming (MILP) formulation where branching at nodes of the tree represent alternative values of the integer or binary variables. The tree is searched by a branch-and-bound algorithm which eliminates a node and the branch that emanates from it if the lower bound of the objective function represented by the terminal nodes of the branch is larger than the current best schedule. The MILP formulation can be stated generically as

$$\begin{aligned} \min \quad & z = cx + fy \\ \text{s.t.} \quad & Ax + By \geq b \\ & x \in \Re_+^n, y \in \{0, 1\}^p \end{aligned}$$

where c, f, b are vector of constants, A and B are matrices of constants, and the solution is defined
Scheduling of Batch Plants, Fig. 4 Trimming the solution tree

by the vector variables x and y. A key feature of using mathematical programming is to represent the relationships implied in Table 1 and Fig. 1 in terms of algebraic descriptions. The advantage of this approach is that a proven optimal solution exists for a problem stated this way. This provides the means to assess the quality of the solution and the impact of implementing the solution. The drawback of this approach is that since binary variables are used to represent the assignment of a batch to a processing unit, and the sequence and timing of processing on each unit, their number grows rapidly with the number of units and the length of the scheduling horizon. However, the performance of modern computing hardware and commercial solvers for MILP problems has allowed industrial size problems to be tackled.

A large variety of modeling paradigms have been developed to produce a MILP solution (Floudas and Lin 2004; Mendez et al. 2006). They address both sequential and networked processes using continuous time or discrete time representations. For sequential processes, time slot approaches have been developed. For networked processes, the resource task network and the state task network have been investigated by many researchers and have been used in industrial applications.

Constraint programming (CP) formulates a problem by writing constraints; but unlike the MILP method, the CP method stresses the feasibility of solutions rather than optimality. Another important difference is that constraints in the CP method do not have to be formulated as algebraic relationships but can be a more general form, thus making it easier in CP to represent complicated constraints. CP processes the constraints sequentially to reduce the space of possible solutions. At each node in the tree, CP processes one constraint after another, reducing the search space at each constraint. Being much newer than mathematical programming, constraint programming has a smaller body of literature to review but excellent performance has been reported in the literature (Baptiste et al. 2001).

In the beam search method, the branch-and-bound algorithm is modified to only evaluate the most promising nodes at any given level of the search tree (Ow and Morton 1988). The number of nodes evaluated is called the beam width and it is a key tuning parameter of the method. Another important element of the method is the technique used to retain nodes for complete evaluation. The technique must balance speed versus thorough evaluation to keep the method practical without discarding promising nodes. The beam search method applied to scheduling has been investigated by many authors (Sabuncuoglu and Bayiz 1999).

Simulation

The simulation approach to scheduling batch plants relies on representing the plant and the relationships inferred by Table 1 in a computer program whose algorithms recreate the behavior of the plant when executed. Generally, the simulators used for batch operations apply discrete event simulation (DES) where entities that have attributes like size, due date, priority, etc. are operated on by activities for a specified duration. Fundamental to DES are the use of queues to hold entities until conditions in the simulation allow them to proceed to their next activity. Time in a DES does not proceed in a continuous manner but rather advances when activities occur. Simulation has the advantage of being able to describe processes and operating policies of arbitrary complexity and model variability in the process operation. Simulators can be used to evaluate manually created schedules or can be combined with optimization and heuristics to produce schedules by simulation-based optimization (Pegden 2011).

An alternative to DES for batch scheduling is the use of multi-agent simulators which are composed of semiautonomous agents assigned to represent the operation of the process and the associated decision making. Each agent has a local goal and communicates with other agents to accomplish it. Like DES, multi-agent simulators are capable of describing very complicated processes. A production schedule can be built through negotiations between agents (Chu et al. 2013).

Selecting a Solution Approach

The selection of the approach for a given batch plant should be value-based, balancing improved revenue with long term cost of ownership by

considering such factors as the technical competency of the production scheduler, the expected capacity utilization of the plant, the operational complexity of the plant, and the cost to maintain the scheduling application. The key is to obtain the least complicated solution by reducing the scheduling problem to the highest level of abstraction and by using the simplest solution method that provides an effective schedule. See Harjunkoski et al. (2013) and Pinedo (2008) for a survey of methods and recommendations for their practical application.

Summary and Future Directions

While there are a great variety of solution methods for scheduling, there are still promising research areas to be investigated. The recent introduction of sophisticated, object oriented process control systems with ties to enterprise management systems sets the stage for the development of automatic, real time scheduling. It is here that the principles of feedback control can be applied to batch plant scheduling. Pursuit of this goal will require continued development of fast, adaptive scheduling methods, real time assessment techniques of schedule performance, and tight integration of scheduling with the process control.

Singular Trajectories in Optimal Control

Bernard Bonnard[1] and Monique Chyba[2]
[1]Institute of Mathematics, University of Burgundy, Dijon, France
[2]University of Hawaii-Manoa, Manoa, HI, USA

Abstract

Singular trajectories arise in optimal control as singularities of the end-point mapping. Their importance has long been recognized, at first in the

Lagrange problem in the calculus of variations where they are lifted into abnormal extremals. Singular trajectories are candidates as minimizers for the time-optimal control problem, and they are parameterized by the maximum principle via a pseudo-Hamiltonian function. Moreover, besides their importance in optimal control theory, these trajectories play an important role in the classification of systems for the action of the feedback group.

Keywords

Abnormal extremals; End-point mapping; Martinet flat case in sub-Riemannian geometry; Pseudo-Hamiltonian

Introduction

The concept of singular trajectories in optimal control corresponds to *abnormal extrema* in optimization. Suppose that a point $x^* \in X \simeq \mathbb{R}^n$ is a point of extremum for a smooth function $\mathcal{L} : \mathbb{R}^n \to \mathbb{R}$ under the equality constraints $F(x) = 0$ where $F : X \to Y$ is a smooth mapping into $Y \simeq \mathbb{R}^p$, $p < n$. The *Lagrange multiplier rule* (Agrachev et al. 1997) asserts the existence of nonzero pairs (λ_0, λ^*) of Lagrange multipliers such that $\lambda_0 \mathcal{L}'(x^*) + \lambda^* F'(x^*) = 0$. The *normality condition* is given by $\lambda_0 \neq 0$, and the abnormal case corresponds to the situation when the rank of $F'(x^*)$ is strictly less than p.

Abnormal extremals have played an important role in the standard calculus of variations (Bliss 1946). Indeed, consider a classical Lagrange problem:

$$\frac{dx}{dt}(t) = F(x(t), u(t)), \ \min_{u(.)} \int_0^T L(x(t), u(t)) dt$$
$$x(0) = x_0, x(T) = x_1,$$

where $x(t) \in X \simeq \mathbb{R}^n$, $u(t) \in \mathbb{R}^m$, F and L are smooth. Using an infinite dimensional framework, the Lagrange multiplier rule still holds and an abnormal extremum corresponds to a singularity of the set of constraints.

Definition

Consider a system of $\mathbb{R}^n$: $\frac{dx}{dt}(t) = F(x(t), u(t))$ where F is a smooth mapping from $\mathbb{R}^n \times \mathbb{R}^m$ into $\mathbb{R}^n$. Fix $x_0 \in \mathbb{R}^n$ and $T > 0$. The *end-point mapping* is the mapping $E^{x_0,T} : u(.) \in \mathcal{U} \to x(T, x_0, u)$ where $\mathcal{U} \subset L^\infty[0, T]$ is the set of admissible controls such that the corresponding trajectory $x(., x_0, u)$ is defined on $[0, T]$. A control $u(.)$ and its corresponding trajectory are called *singular* on $[0, T]$ if $u(.) \in \mathcal{U}$ is such that the Fréchet derivative $E'^{x_0,T}$ of the end-point mapping is not of full rank n at $u(.)$.

Fréchet Derivative and Linearized System

Given a reference trajectory $x(.)$, $t \in [0, T]$, associated to $u(.)$ with $x(0) = x_0$, and solution of $\frac{dx}{dt}(t) = F(x(t), u(t))$, the system

$$\dot{\delta x}(t) = A(t)\delta x(t) + B(t)\delta u(t)$$

with

$$A(t) = \frac{\partial F}{\partial x}(x(t), u(t)), \ B(t) = \frac{\partial F}{\partial u}(x(t), u(t))$$

is called the *linearized system* along the control-trajectory pair $(u(.), x(.))$.

Let $M(t)$ be the fundamental matrix, $t \in [0, T]$ solution of

$$\dot{M}(t) = A(t)M(t), \qquad M(0) = I_n.$$

Integrating the linearized system with $\delta x(0) = 0$, one gets the following proposition.

Proposition 1 *The Fréchet derivative of $E^{x_0,T}$ at $u(.)$ is given by*

$$E_u'^{x_0,T}(v) = M(T) \int_0^T M^{-1}(t)B(t)v(t) dt.$$

S

Computation of the Singular Trajectories and Pontryagin Maximum Principle

According to the previous computations, a control $u(.)$ with corresponding trajectory $x(.)$ is singular on $[0, T]$ if the Fréchet derivative $E'^{x_0,T}$ is not of full rank at $u(.)$. This is equivalent to the condition that the linearized system is *not controllable* (Lee and Markus 1967).

Such a condition is difficult to verify directly since the linearized system is time-depending and the computation is associated to the Maximum Principle (Pontryagin et al. 1962).

Let p^* be a nonzero vector such that p^* is orthogonal to $\text{Im}(E'^{x_0,T})$ and let $p(t) = p^* M(T) M^{-1}(t)$; then $p(.)$ is solution of the *adjoint system*

$$\dot{p}(t) = -p(t)\frac{\partial F}{\partial u}(x(t), u(t))$$

and satisfies almost everywhere the equality

$$p(t)\frac{\partial F}{\partial u}(x(t), u(t)) = 0.$$

Introduce the *pseudo-Hamiltonian* $H(x, p, u) = \langle p, F(x, u) \rangle$, where $\langle ., . \rangle$ is the Euclidean inner product, one gets the following characterization.

Proposition 2 *If (x, u) is a singular control-trajectory pair on $[0, T]$, then there exists a nonzero adjoint vector $p(.)$ defined on $[0, T]$ such that (x, p, u) is solution a.e. of the following equations:*

$$\frac{dx}{dt} = \frac{\partial H}{\partial p}(x, p, u), \ \frac{dp}{dt} = -\frac{\partial H}{\partial x}(x, p, u)$$

$$\frac{\partial H}{\partial u}(x, p, u) = 0.$$

Application to the Lagrange Problem

Consider the problem

$$\frac{dx}{dt}(t) = F(x(t), u(t)), \min \int_0^T L(x(t), u(t)) dt$$

with $x(0) = x_0$, $x(T) = x_1$.

Introduce the *cost-extended pseudo-Hamiltonian*: $\tilde{H}(x, p, u) = \langle p, F(x, u) \rangle + p_0 L(x, u)$; it follows that the maximum principle is equivalent to the Lagrange multiplier rule presented in the introduction:

$$\frac{d\tilde{x}}{dt} = \frac{\partial \tilde{H}}{\partial \tilde{p}}(\tilde{x}, \tilde{p}, u), \frac{d\tilde{p}}{dt} = -\frac{\partial \tilde{H}}{\partial \tilde{x}}(\tilde{x}, \tilde{p}, u)$$

$$\frac{\partial \tilde{H}}{\partial u}(\tilde{x}, \tilde{p}, u) = 0$$

where $\tilde{x} = (x, x^0)$ is the extended state variable solution of $\frac{dx}{dt} = F(x, u), \frac{dx^0}{dt} = L(x, u)$ and $\tilde{p} = (p, p_0)$ is the extended adjoint vector. One has the condition $\langle \tilde{p}, \tilde{E}_u'^{x_0,T}(v) \rangle = 0$ where $\tilde{E}^{x_0,T}$ is the cost-extended end-point mapping.

The Role of Singular Extremals in Optimal Control

While the traditional treatment in optimization of singular extremals is to consider them as a pathology, in modern optimal control, they play an important role which is illustrated by two examples from *geometric optimal control*.

Singular Trajectories in Quantum Control

Up to a normalization (Lapert et al. 2010), the time minimization *saturation problem* is to steer in minimum time the magnetization vector $M = (x, y, z)$ from the north pole of the Bloch Ball $N = (0, 0, 1)$ to its center $O = (0, 0, 0)$. The evolution of the system is described by the *Bloch equation* in nuclear magnetic resonance (Levitt 2008)

$$\frac{dx}{dt} = -\Gamma x + u_2 z$$

$$\frac{dy}{dt} = -\Gamma - u_1 z$$

$$\frac{dz}{dt} = \gamma(1 - z) + u_1 y - u_2 x$$

where (Γ, γ) are proportional to the inverse of the relaxation times and $u = (u_1, u_2)$ is the control radio frequency-magnetic field bounded according to $|u| \leq M$. Due to the z-symmetry of revolution, one can restrict the problem to the 2D single-input case

$$\frac{dy}{dt} = -\Gamma y - uz, \frac{dz}{dt} = \gamma(1 - z) + uy$$

that can be written as $\frac{dq}{dt} = F(q) + uG(q)$.

According to the maximum principle, the time-optimal solutions are the concatenations of *regular extremals* for which $u(t) = M \operatorname{sign}\langle p(t), G(q(t)) \rangle$ and singular arcs where $\langle p(t), G(q(t)) \rangle = 0, \forall t$, and $p(t)$ is solution of the adjoint system. Differentiating with respect of time and using the *Lie bracket* notation $[X, Y](q) = \frac{\partial X}{\partial q}(q)Y(q) - \frac{\partial Y}{\partial q}(q)X(q)$, we get

$$\langle p, [G, F](q) \rangle = 0,$$

$$\langle p, [[G, F], G](q) \rangle + u \langle p, [[G, F], F](q) \rangle = 0.$$

This leads to two singular arcs:
- The vertical line $y = 0$, corresponding to the z-axis of revolution
- The horizontal line $z = \frac{\gamma}{2(\gamma - \Gamma)}$

The interesting physical case is when $2\Gamma > 3\gamma$ where the vertical singular line is such that $-1 < \frac{\gamma}{2(\gamma - \Gamma)} < 0$. In this case, the time minimum solution is represented on Fig. 1. On Fig. 2 we draw the experimental solution in the deoxygenated blood case, compared with the standard inversion recovery sequence.
Singular Trajectories in Optimal Control, Fig. 1 The computed optimal solution is the following concatenation: bang arc σ'_M with the horizontal singular arc σ_{sh} followed by a bang arc P and finally the singular vertical arc σ_{sv}

Abnormal Extremals in SR Geometry

Sub-Riemannian geometry was introduced by R.W. Brockett as a generalization of Riemannian geometry (Brockett 1982; Montgomery 2002) with many applications in control (for instance, in motion planning (Bellaiche et al. 1998; Gauthier and Zakalyukin 2006) and quantum control). Its formulation in the framework of control theory is

$$\dot{q}(t) = \sum_{i=1}^{m} u_i(t) F_i(q(t)), \quad \min_{u(.)} \int_0^T (\sum_{i=1}^{m} u_i^2(t) dt)$$

where $q \in U$ open set in $\mathbb{R}^n$, $m < n$ and $F_1, \cdots, F_m$ are smooth vector fields which forms an orthonormal basis of the distribution they generate.

According to the maximum principle, normal extremals are solutions of the Hamiltonian vector field $\mathbf{H}_n$, $H_n = \frac{1}{2}(\sum_{i=1}^{m} H_i(q, p)^2)$, $H_i = \langle p, F_i(q) \rangle$ for $i = 1, \cdots m$. Again abnormal extremals can be computed by differentiating the constraint $H_i = 0$ along the extremals. Their first occurrence takes place in the so-called Martinet flat case: $n = 3, m = 2, F_1, F_2$ are given by

$$F_1 = \frac{\partial}{\partial x} + \frac{y^2}{2}\frac{\partial}{\partial z}, F_2 = \frac{\partial}{\partial y}$$

where $q = (x, y, z) \in U$ neighborhood of the origin, and the metric is given by $ds^2 = dx^2 + dy^2$. The singular trajectories are contained in the Martinet plane $M : y = 0$ and are the lines $z = z_0$. An easy computation shows that they are optimal for the problem. We represent below the role of the singular trajectories when computing the sphere of small radius, from the origin, intersected with the Martinet plane (Fig. 3).

Summary and Future Directions

Singular trajectories play an important role in many optimal control problem such as in quantum control and cancer therapy (Schättler and Ledzewicz 2012). They have to be carefully analyzed in any applications; in particular in

Singular Trajectories in Optimal Control, Fig. 2 Experimental result. Usual inversion sequence in *green*, optimal computed sequence in *blue*
Singular Trajectories in Optimal Control, Fig. 3 Projection of the SR sphere on the xz-plane. The singular line is $x = t$ and the picture shows the pinching of the SR sphere in the singular direction

Boscain and Piccoli (2006) the authors provide for single-input systems in two dimensions a classification of optimal synthesis with singular arcs.

Additionally, from a theoretical point of view, singular trajectories can be used to compute feedback invariants for nonlinear systems (Bonnard and Chyba 2003). In relation, a purely mathemat-

ical problem is the classification of distributions describing the nonholonomic constraints in sub-Riemannian geometry (Montgomery 2002).

Small Signal Stability in Electric Power Systems

Vijay Vittal
Arizona State University, Tempe, AZ, USA

Abstract

Small signal rotor angle stability analysis in power systems is associated with insufficient damping of oscillations under small disturbances.

Rotor angle oscillations due to insufficient damping have been observed in many power systems around the world. This entry overviews the predominant approach to examine small signal rotor angle stability in large power systems using eigenvalue analysis.

Keywords

Small Signal Rotor Angle Stability in Power Systems

As power system interconnections grew in number and size, automatic controls such as voltage regulators played critical roles in enhancing reliability by increasing the synchronizing capability between the interconnected systems. As technology evolved the capabilities of voltage regulators to provide synchronizing torque following disturbances were significantly enhanced. It was, however, observed that voltage regulators tended to reduce damping torque, as a result of which the system was susceptible to rotor angle oscillatory instability. An excellent exposition of the mechanism and the underlying analysis is provided in the textbooks (Anderson and Fouad 2003; Sauer and Pai 1998; Kundur 1993), and a number of practical aspects of the analysis are detailed in Eigenanalysis and Frequency Domain Methods for System Dynamic Performance (1989) and Rogers (2000). Two types of rotor angle oscillations are commonly observed. Low-frequency oscillations involving synchronous machines in different operating areas are commonly referred to as inter-area oscillations. These oscillations are typically in the 0.1–2 Hz frequency range. Oscillations between local machines or a group of machines at a power plant are referred to as plant mode oscillations. These oscillations are typically above the 2 Hz frequency range. The modes associated with rotor angle oscillations are also termed inertial modes of oscillation. Other modes of oscillations associated with the various

S

controls also exist. With the integration of significant new wind and photovoltaic generation which are interconnected to the grid using converters, new modes of oscillation involving the converter controls and conventional synchronous generator states are being observed.

The basis for small signal rotor angle stability analysis is that the disturbances considered are small enough to justify the use of linear analysis to examine stability (Kundur et al. 2004). As a result, Lyapunov's first method Vidyasagar (1993) provides the analytical underpinning to analyze small signal stability. Eigenvalue analysis is the predominant approach to analyze small signal rotor angle stability in power systems. Commercial software packages that utilize sophisticated algorithms to analyze large-scale power systems with the ability to handle detailed models of power system components exist.

The power system representation is described by a set of nonlinear differential algebraic equations shown in (1)

$$\dot{x} = f(x, z)$$
$$0 = g(x, z) \tag{1}$$

where x is the state vector and z is a vector of algebraic variables. Small signal stability analysis involves the linearization of (1) around a system operating point which is typically determined by conducting a power flow analysis:

$$\begin{bmatrix} \Delta \dot{x} \\ 0 \end{bmatrix} = \begin{bmatrix} J_1 & J_2 \\ J_3 & J_4 \end{bmatrix} \begin{bmatrix} \Delta x \\ \Delta z \end{bmatrix} \tag{2}$$

The power system state matrix can be obtained by eliminating the vector of algebraic variables Δz in (2)

$$\Delta \dot{x} = \left(J_1 - J_2 J_4^{-1} J_3 \right) \Delta x = A \Delta x \tag{3}$$

where A represents the system state matrix. Based on Lyapunov's first method, the eigenvalues of A characterize the small signal stability behavior of the nonlinear system in a neighborhood of the operating point around which the system is linearized. The eigenvectors corresponding to the eigenvalues also provide

significant qualitative information. For each eigenvalue λ_i, there exists a vector u_i known as the right eigenvector of A which satisfies the equation

$$A u_i = \lambda_i u_i \tag{4}$$

There also exists a row vector v_i known as the left eigenvector of A which satisfies

$$v_i A = \lambda_i v_i \tag{5}$$

For a system which has distinct eigenvalues, the right and left eigenvectors form an orthogonal set governed by

$$\begin{aligned} v_i u_j &= k_{ij} \\ \text{where} \\ k_{ij} &\neq 0 \ i = j \\ k_{ij} &= 0 \ i \neq j \end{aligned} \tag{6}$$

One set (either right or left) of eigenvectors are usually scaled to unity and the other set obtained by solving (6) with $k_{ij} = 1$. The right eigenvectors can be assembled together as columns of a square matrix U, and the corresponding left eigenvectors can be assembled as rows of a matrix V; then

$$V = U^{-1} \tag{7}$$

and

$$VAU = \Lambda \tag{8}$$

where Λ is a diagonal matrix with the distinct eigenvalues as the diagonal entries. The relationship in (8) is a similarity transformation and in the case of distinct eigenvalues provides a pathway to obtain solutions to the linear system of equations (3). Applying the following similarity transformation to (3)

$$\Delta x = U z \rightarrow \Delta x_i(t) = \sum_{j=1}^{n} u_{ij} z_j e^{\lambda_j t} \tag{9}$$

$$U \dot{z} = A U z \tag{10}$$

$$\dot{z} = U^{-1} A U z = V A U z = \Lambda z \tag{11}$$

$$\dot{z}_i(t) = \lambda_i z_i \Rightarrow z_i(t) = z_i(0) e^{\lambda_i t} \tag{12}$$

$$z_i(0) = v_i^T \Delta x(0) \tag{13}$$

$$z_i\,(t) = v_i^T \,\Delta x\,(0)\,e^{\lambda_i t} \qquad (14)$$

From (9) and (14), it can be observed that the right eigenvector describes how each mode of the system is distributed throughout the state vector (and is referred to as the mode shape), and the left eigenvector in conjunction with the initial conditions of the system state vector determines the magnitude of the mode. The right eigenvector or the mode shape has been often used to identify dynamic patterns in small signal dynamics. One problem with the mode shape is that it is dependent on the units and scaling of the state variables as a result of which it is difficult to compare the magnitudes of entries that are disparate and correspond to states that impact the dynamics differently. This resulted in the development of the participation factors (Pérez-Arriaga et al. 1982) which are dimensionless and independent of the choice of units. The participation factor is expressed as

$$p_{ik} = v_{ik} u_{ik} \qquad (15)$$

The magnitude of the participation factor measures the relative participation of the ith state variable in the kth mode and vice versa.

Small Signal Stability Analysis Tools for Large Power Systems

Efficient software tools exist that facilitate the application of the methods in section "Small Signal Rotor Angle Stability in Power Systems" to large power systems (Powertech 2012; Martins 1989). These tools incorporate detailed models of power system components and also leverage the sparsity in power systems. The building of the A matrix is a complex task for large power systems with a multitude of dynamic components. The approach in Powertech (2012) utilizes a technique where state space equations are developed for each dynamic component in the system using a solved power flow solution and the dynamic data description for a given system. These state space equations are then coupled based on the system topology, and the system A matrix is derived as in (3). Reference Martins (1989) takes advan-

tage of the sparsity of the Jacobian matrix in (2) and develops efficient algorithms to determine the eigenvalues and eigenvectors. The software tools also provide the flexibility of a number of different options with regard to eigenvalue computations:

1. Calculation of a specific eigenvalue at a specified frequency or with a specified damping ratio
2. Simultaneous calculation of a group of relevant eigenvalues in a specified frequency range or in specified damping ratio range

In addition to the features described above, commercial software packages also provide features to evaluate:

1. Frequency response plots
2. Participation factors
3. Transfer functions, residues, controllability, and observability factors
4. Linear time response to step changes
5. Eigenvalue sensitivities to changes in specified parameters

Applications of Small Signal Stability Analysis in Power Systems

Small signal stability analysis tools are used for a range of applications in power systems. These applications include:

Analysis of local stability problems – These types of stability problems are primarily associated with the tuning of control associated with the synchronous generator, converter interconnected renewable resources, and HVDC link current control. In certain cases analysis of local stability problems could also involve design of supplementary controllers which enhance the stability region. Since the stability problem pertains to a local portion of the power system, there is significant flexibility in modeling the system. In many instances local stability problems facilitate the use of a simple representation of a power system which could include the particular machine or a local group of machines in question together with a highly equivalenced representation of the rest of the system. In cases where controls other than generator controls influence stability, e.g.,

S

static VAr compensators or HVDC links, the system representation would need to be extended to include portions of the system where these devices are located. Typical small signal stability problems that are analyzed include:

1. Power system stabilizer design
2. Automatic voltage regulator tuning
3. Governor tuning
4. DC link current control
5. Small signal stability analysis for subsynchronous resonance
6. Load modeling effects on small signal stability

References Eigenanalysis and Frequency Domain Methods for System Dynamic Performance (1989) and Rogers (2000) provide comprehensive examples of the analysis conducted for each of the problems listed above.

Analysis of global stability problems – These types of stability problems are associated with controls that impact generators located in different areas of the power systems. The analysis of these inter-area problems requires a more systematic approach and involves representation of the power system in greater detail. The problems that are analyzed under this category include:

1. Power system stabilizer design
2. HVDC link modulation
3. Static VAr compensator controls

References Eigenanalysis and Frequency Domain Methods for System Dynamic Performance (1989) and Rogers (2000) again provide details of the analysis conducted for each of the problems listed under this category.

Spatial Description of Biochemical Networks

Pablo A. Iglesias
Electrical & Computer Engineering, The Johns Hopkins University, Baltimore, MD, USA

Abstract

Many biological behaviors require that biochemical species be distributed spatially throughout the cell or across a number of cells. To explain these situations accurately requires a spatial description of the underlying network. At the continuum level, this is usually done using reaction-diffusion equations. Here we demonstrate how this class of models arises. We also show how the framework is used in two popular models proposed to explain spatial patterns during development.

Keywords

Diffusion; Morphogen gradient; Pattern formation; Reaction-diffusion; Turing instability

Introduction

Cells are complex environments consisting of spatially segregated entities, including the nucleus and various other organelles. Even within these compartments, the concentrations of various biochemical species are not homogeneous, but can vary significantly. The proper localization of proteins and other biochemical species to their respective sites is important for proper cell function. This can be because the spatial distribution of signaling molecules itself confers information, such as when a cell needs to respond to a spatially graded cue to guide its motion (Iglesias and Devreotes 2008) or growth pattern (Lander 2013). Alternatively, information that is obtained in one part of the cell must be transmitted to another part of the cell, as when receptor-ligand binding at the cell surface leads to transcriptional responses in the nucleus. Frequently, describing the action of a biological network accurately requires not only that one account for the chemical interactions between the different components but that the spatial distribution of the signaling molecules also be considered.

Accounting for Spatial Distribution in Models

Mathematical models of biological networks usually assume that reactions take place in well-stirred vessels in which the concentrations of the interacting species are spatially homogeneous and hence need not be accounted for explicitly. These systems also assume that the volume is constant. When the spatial location of molecules in cells is important, the concentration of species changes in both time and space.

Compartmental Models
One way to account for spatial distribution of signaling components is through compartmental models. As the name suggests, in these models the cell is divided into different regions that are segregated by membranes. Within each compartment, the concentration of the network species

is assumed to be spatially homogeneous. The membranes in these models can be assumed to be either permeable or impermeable. In permeable membranes, information passes through small openings, such as ion channels or nuclear pores, which allow molecules to move from one side of the membrane to the other. With impermeable membranes, information must be transduced by transmembrane signaling elements, such as cell-surface receptors, that bind to a signaling molecule in one side of the membrane and release a secondary effector on the other side. Note that in this case, the membrane itself acts as a third compartment.

Compartmental models offer simplicity, since the reactions that happen in a single region obey the same reaction kinetics usually assumed in spatially homogeneous models. Even when the reactions involve more than one compartment, as in ligand-receptor binding, this can still be described by the usual reaction dynamics. Care must be taken, however, to account properly for the different effects on the respective concentrations as molecules move from one compartment to another. In models of spatially homogeneous systems, there is little practical difference between writing the ordinary-differential equations in terms of molecule numbers or concentrations, since the two are proportional to each other according to the volume, which is constant. In a compartmental model, if the molecule moves from one compartment to another, there is conservation of molecule numbers, but not concentrations. For example, if a species is found in two compartments with volumes V_1 and V_2 and transfer rates k_{12} and k_{21} s^{-1}, then the differential equations describing transport between compartments can be expressed in terms of numbers (n_1 and n_2) as follows:

$$\frac{dn_1}{dt} = -k_{12}n_1 + k_{21}n_2$$
$$\frac{dn_2}{dt} = +k_{12}n_1 - k_{21}n_2.$$

Dividing by the respective volumes ($C_1 = n_1/V_1$ and $C_2 = n_2/V_2$), we obtain equations for the concentrations

$$\frac{dC_1}{dt} = -k_{12}C_1 + k_{21}(\tfrac{V_2}{V_1})C_2$$

$$\frac{dC_2}{dt} = +k_{12}(\tfrac{V_1}{V_2})C_1 - k_{21}C_2.$$

In the former case, the two equations add to zero, indicating that $n_1(t) + n_2(t) =$ constant. In the latter, if $V_1 \neq V_2$, then $C_1(t) + C_2(t)$ varies over time as molecules move from one compartment to the other.

Diffusion and Advection

If the distribution of molecules inside any single compartment is spatially heterogeneous, then models must account for this spatial distribution. At the continuum level, this is done using reaction-diffusion equations. The basic assumption is a conservation principle expressed as a continuity equation:

$$\frac{\partial \rho}{\partial t} + \nabla j = f,$$

which relates the changes in the density (ρ) of a conserved quantity (in our case, the concentration of a species: $\rho = C$) to the flux j and any net production f. In biological networks, the latter represents the net effect of all the reactions that affect the concentration of the species including binding, unbinding, production, degradation, post-translational modifications, etc.

In biological models, the flux term usually comes from one of two sources: diffusion or advection. According to Fick's law, diffusive flux is proportional to the negative gradient of the concentration of the species as particles move from regions of high concentration to regions of low concentration. The coefficient of proportionality is the diffusion coefficient, D:

$$j_{\text{diff}} = -D\nabla C.$$

Fick's law describes thermally driven Brownian motion of molecules at the continuum level. If the species is embedded in a moving field, then the flux is proportional to the velocity of the underlying fluid. In this case, we have advective flow:

$$j_{\text{adv}} = vC.$$

In biological systems, advection can arise because of the movement of the cytoplasm, but it can also represent directed transport of molecules, such as the movement of cargo along filaments by processive motors. In general, molecules exhibit both diffusive and advective motion: $j = j_{\text{diff}} + j_{\text{adv}}$, leading to

$$\frac{\partial C}{\partial t} + \nabla(-D\nabla C + vC) = f,$$

which, under the assumption that the diffusion coefficient and the transport velocity are independent of spatial location, leads to the reaction-diffusion-advection equation:

$$\frac{\partial C}{\partial t} = D\nabla^2 C - v\nabla C + f.$$

Being a second-order partial differential, the solution requires an initial condition and two boundary conditions. Common choices for the latter include periodic (e.g., in models of closed boundaries) or no-flux (to describe the impermeability of membranes) assumptions.

Measuring Diffusion Coefficients

Invariably, solving the reaction-diffusion equation requires knowledge of the diffusion coefficient of the molecule. Experimentally, this can be done in a number of ways. In fluorescence recovery after photobleaching (FRAP), a laser is used to photobleach normally fluorescent molecules in a specific area of the cell. As these "dark" molecules are replaced by fluorescent molecules from non-bleached areas, the fluorescent intensity of the bleached area recovers. Higher diffusion leads to faster recovery. The time to half recovery, $\tau_{1/2}$, can be used to estimate D. If recovery occurs by lateral diffusion, then

$$D = \frac{r_0^2 \gamma}{4\tau_{1/2}}$$

where r_0 is the $1/e^2$ radius of the Gaussian profile laser beam and γ is a parameter that depends on the extent of photobleaching, which ranges from 1 to 1.2 (Chen et al. 2006).

These days, it is increasingly common to measure lateral diffusion coefficients by observing the trajectory of single molecules. A molecule with diffusion coefficient D undergoing Brownian motion in a two-dimensional environment is expected to have mean-square displacement (MSD) equal to

$$\langle r^2 \rangle = 4Dt.$$

Thus, the coefficient D can be obtained by measuring how the MSD changes as a function of the time interval t. This method can also show if the molecule is undergoing advection in which case

$$\langle r^2 \rangle = 4Dt + v^2 t^2.$$

This super-diffusive behavior can be seen in the concave nature of the plot of $\langle r^2 \rangle$ against t. This plot will also reveal barriers to diffusion. For example, if the molecule is confined to move in a circular region of radius a, then, as t increases, $\langle r^2 \rangle$ cannot exceed a^2.

Both these methods work best for molecules diffusing on a membrane. For molecules diffusing in the cytoplasm, the three-dimensional imaging required is considerably more difficult, particularly since the diffusion of particles in the cytoplasm ($D \sim 1\text{--}10\,\mu\text{m}^2\,\text{s}^{-1}$) is usually orders of magnitude greater than for membrane-bound proteins ($D \sim 0.01\text{--}0.1\,\mu\text{m}^2\,\text{s}^{-1}$). In this case, an analytical expression can be used to estimate the diffusion coefficient. The diffusion coefficient of a spherical particle of radius r moving in a low Reynolds number liquid with viscosity η is given by the Stokes-Einstein equation:

$$D = \frac{k_B T}{6\pi \eta r}.$$

The exact viscosity of the cell is unknown, but estimates that η is approximately five times that of water lead to diffusion coefficients of cytoplasmic proteins that match those measured using FRAP.

Diffusion-Limited Reaction Rates

Even in compartments that are considered well stirred, the diffusion of molecules is necessary for reactions to take place. In particular, before two molecules can react, they must come together. To see how diffusion influences this, suppose that spherical molecules of species A and B with radii r_A and r_B, respectively, come together to form a complex AB at a rate k_d. This rate represents the likelihood that molecules of A and B collide at random and hence will depend on the diffusion properties of the two species. The molecules in this complex can dissociate at rate k_d' or can be converted to species C at rate k_r. Thus, the overall reaction involves two steps:

$$A + B \underset{k_d'}{\overset{k_d}{\rightleftharpoons}} AB$$

$$AB \xrightarrow{k_r} C.$$
Assuming that the system is at quasi-steady-state, that is, the concentration of AB is constant, the effective rate of production C is given by

$$k_{\text{eff}} = \frac{k_d k_r}{k_d' + k_r}.$$

There are two regions of operation. If $k_d' \gg k_r$, then $k_{\text{eff}} \approx k_r(k_d/k_d')$. In this case production is said to be reaction limited. If $k_d' \ll k_r$, then $k_{\text{eff}} \approx k_d$ and production is diffusion limited. In this case, it is possible to find k_d as a function of the species' diffusion coefficients.

Assume that species A is stationary, in which case the effective diffusion is the sum of the two diffusion coefficients: $D = D_A + D_B$. The concentration of species B depends on the distance away from molecules of A. Because we assume that the reaction rate is fast, at the point of contact ($r^\star = r_A + r_B$) the concentration is zero since any molecules of AB are quickly converted to C. At the other extreme, as $r \to \infty$, the concentration approaches the bulk concentration B_0. According to Fick's law, this concentration gradient causes a flux density given by $j = -D(\partial B/\partial r)$. The total flux into a sphere of radius r is then

$$J = 4\pi r^2 j = -4\pi D r^2 \frac{\partial B}{\partial r},$$

which, at steady state, is constant. Solving this equation for $B(r)$ using the two boundary equations leads to a flux

$$J = -4\pi D B_0 r^\star,$$

from which we have that

$$k_d = 4\pi D r^\star.$$

A typical value for k_d, using the Einstein-Stokes formula, is

$$4\pi \left(2 \times \frac{k_B T}{6\pi \eta (r^\star/2)} \right) r^\star = \frac{8 k_B T}{3\eta}$$
$$\approx 10^3 \, \mu\mathrm{m}^{-1} \, \mathrm{s}^{-1}.$$

Spatial Patterns

The effect of spatial heterogeneities has been of long interest to developmental biologists, who study how spatial patterns arise. Two distinct models have been proposed to explain how this patterning can arise. Here we introduce these models and discuss their relative merits. Though usually seen as competing models, there is recent evidence suggesting that both models may play complementary roles during development (Reth et al. 2012).

Morphogen Gradients

A morphogen is a diffusible molecule that is produced or secreted at one end of an organism. Diffusion away from the localized source forms a concentration gradient along the spatial dimension. Morphogens are used to control gene expression of cells lying along this spatial domain. Thus, a morphogen gradient gives rise to spatially dependent expression profiles that can account for spatial developmental patterns (Rogers and Schier 2011).

The mathematics behind the formation of a morphogen gradient are relatively straightforward. The concentration of the morphogen is denoted by $C(x, t)$. There is a constant flux (j_0) at one end ($x = 0$) of a finite one-dimensional

domain of length L, but the morphogen cannot exit at the other end. The species diffuses inside the domain and also decays at a rate proportional to its concentration ($f = -kC$). Thus, the concentration is governed by the reaction-diffusion equation:

$$\frac{\partial C}{\partial t} = D \frac{\partial^2 C}{\partial x^2} - kC,$$

with boundary conditions: $D \frac{\partial C}{\partial x} = -j_0$ at $x = 0$, and $D \frac{\partial C}{\partial x} = 0$ at $x = L$. We focus on the steady state:

$$\frac{\mathrm{d}^2 \bar{C}}{\mathrm{d}x^2} = \frac{k}{D} \bar{C},$$

so that the initial condition is not important. In this case, the distribution of the species is given by

$$\bar{C}(x) = \frac{\lambda j_0}{D} \frac{\cosh([L - x]/\lambda)}{\sinh(L/\lambda)}.$$

Thus, the shape of the gradient is roughly exponential with parameter $\lambda = \sqrt{D/k}$, known as the dispersion, which specifies the average distance that molecules diffuse into the domain before they are degraded or inactivated. Equally important in determining the gradient, however, is the spatial dimension (L) relative to the dispersion, $\Phi = L/\lambda$, a ratio known as the Thiele modulus. If $\Phi \ll 1$, then the concentration will be approximately homogeneous. Alternatively, $\Phi \gg 1$ leads to a sharp transition close to the boundary where there is flux and a relatively flat concentration thereafter.

Though morphogen gradients are commonly used to describe signaling during development, where the gradient can extend across a number of cells, the mathematics described above are equally suitable for describing concentration gradients of intracellular proteins. In this case, the dimension of the cell has a significant effect on the shape of the gradient (Meyers et al. 2006).

As discussed above, morphogen gradients are established in an open-loop mode. As such, the actual concentration experienced at a point downstream of the source of the morphogen will vary depending on a number of parameters, including the flux j_0 and the rate of degradation k.

Moreover, because the concentration of the morphogen decreases as the distance from the source grows, the relative stochastic fluctuations will increase. How to manage this uncertainty is an active area of research (Rogers and Schier 2011; Lander 2013).

Diffusion-Driven Instabilities

In 1952, Alan Turing proposed a model of how patterns could arise in biological systems (Turing 1952). His interest was in explaining how an embryo, initially spherical, could give rise to a highly asymmetric organism. He posited that the breaking of symmetry could be a result of the change in the stability of the homogeneous state of the network which would amplify small fluctuations inherent in the initial symmetry. Turing sought to explain how these instabilities could arise using only reaction-diffusion systems.

To illustrate how diffusion-driven instabilities can arise, we work with a single two-species linear reaction network:

$$\frac{\partial}{\partial t} \begin{bmatrix} C_1 \\ C_2 \end{bmatrix} = A \begin{bmatrix} C_1 \\ C_2 \end{bmatrix} + \frac{\partial^2}{\partial x^2} D \begin{bmatrix} C_1 \\ C_2 \end{bmatrix}$$

where $A = \begin{bmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{bmatrix}$ specifies the reaction terms and the diagonal matrix $D = \begin{bmatrix} D_1 & 0 \\ 0 & D_2 \end{bmatrix}$ the diffusion coefficients.

We assume that, in the absence of diffusion, the system is stable, so that $\det(A) > 0$ and $\text{trace}(A) < 0$. When considering diffusion in a one-dimensional environment of length L, we must consider the spatial modes, which are of the form $\exp(iqx)$. In this case, stability of the system requires that $\text{trace}(A - q^2 D) < 0$ and $\det(A - q^2 D) > 0$. The former is always true, since $\text{trace}(A - q^2 D) = \text{trace}(A) - q^2(D_1 + D_2) < \text{trace}(A) < 0$. However, the condition on the determinant can fail since

$$\det(A - q^2 D) = D_1 D_2 q^4 - q^2(a_{22}D_1 + a_{11}D_2)$$
$$+ \det(A). \tag{1}$$

Since $\det(A) > 0$, diffusion-driven instabilities can only occur if the term $a_{22}D_1 + a_{11}D_2 > 0$, by which it follows that at least one of a_{11} or a_{22}

must be positive. Since $\text{trace}\, A < 0$, it follows that the diagonal terms must have opposite sign. Usually, it is assumed that $a_{11} > 0$ and that $a_{22} < 0$. Since $\det(A) > 0$, it follows that a_{12} and a_{21} must also have opposite sign.

These requirements in the sign pattern of the two molecules lead to one of two classes of systems. In the first class, known as activator/inhibitor systems, the activator (assume species 1) is autocatalytic ($a_{11} > 0$) and also stimulates the inhibitor ($a_{21} > 0$), which negatively regulates the activator ($a_{12} < 0$). In the other class, known as substrate-depletion systems, a product (species 1) is autocatalytic ($a_{11} > 0$), but in its production consumes ($a_{21} < 0$) the substrate (species 2) whose presence is needed for formation of the product ($a_{12} > 0$). Note that both systems involve an autocatalytic positive feedback loop ($a_{11} > 0$), as well as a negative feedback loop involving both species ($a_{12}a_{21} < 0$).

The stability condition also imposes a necessary condition on the dispersion of the two species, ($\lambda_i = \sqrt{D_i/|a_{ii}|}$), since

$$a_{22}D_1 + a_{11}D_2 > 0 \quad \Longrightarrow \quad -\lambda_1^2 + \lambda_2^2 > 0$$

Thus, the species providing the negative feedback (inhibitor or substrate) must have higher dispersion ($\lambda_2 > \lambda_1$). This requirement is usually referred to as local activation and long-range inhibition.

These conditions are necessary, but not sufficient. They ensure that the parabola defined by Eq. 1 has real roots. However, when diffusion takes place in finite domains, the parameter q can only take discrete values $q = 2\pi n/L$ for integers n. Thus, for a spatial mode to be unstable, it must be that $\det(A - q^2 D) < 0$ at specific values of q corresponding to integers n. If the dimension of the domain is changing, as would be expected in a growing domain, the parameter q^2 will decrease over time suggesting that higher modes may lose stability. Thus, the nature of the pattern may evolve over time.

Over the years, Turing's framework has been a popular model among theoretical biologists and has been used to explain countless patterns

seen in biological systems. It has not had the same level of acceptance among biologists, likely because of the difficulty of mapping a complex biological system involving numerous interacting species into the simple nature of the theoretical model (Kondo and Miura 2010).

Summary and Future Directions

Spatial aspects of biochemical signaling are increasingly playing a role in the study of cellular signaling systems. Part of this interest is the desire to explain spatial patterns seen in sub-cellular localizations observed through live cell imaging using fluorescently tagged proteins. The ever-increasing computational power available for simulations is also facilitating this progress. Specially built spatial simulation software, such as the Virtual Cell, is freely available and tailor-made for biological simulations enabling simulation of spatially varying reaction networks in cells of varying size and shape (Cowan et al. 2012).

Of course, cell shapes are not static, but evolve in large part due to the effect of the underlying biochemical system. This requires simulation environments that solve reaction-diffusion systems in changing morphologies. This has received considerable interest in modeling cell motility (Holmes and Edelstein-Keshet 2013).

Another aspect of spatial models that is only now being addressed is the role of mechanics in driving spatially dependent models. For example, it has recently been shown that the interaction between biochemistry and biomechanics can itself drive Turing-like instabilities (Goehring and Grill 2013).

Finally, we note that our discussion of spatially heterogeneous signaling has been based on continuum models. As with spatially invariant systems, this approach is only valid if the number of molecules is sufficiently large that the stochastic nature of the chemical reactions can be ignored. In fact, spatial heterogeneities may lead to localized spots requiring a stochastic approach, even though the molecule numbers are such that a continuum approach would be acceptable if the

cell were spatially homogeneous. The analysis of stochastic interactions in these systems is still much in its infancy and is likely to be an increasingly important area of research (Mahmutovic et al. 2012).

Spectral Factorization

Michael Sebek
Department of Control Engineering, Faculty of
Electrical Engineering, Czech Technical
University in Prague, Prague 6, Czech Republic

Abstract

For more than half a century, spectral factorization is encountered in various fields of science and engineering. It is a useful tool in robust and optimal control and filtering and many other areas. It is also a nice control-theoretical concept closely related to Riccati equation. As a quadratic equation in polynomials, it is a challenging algebraic task.

Keywords

Controller design; H_2-optimal control; H_∞-optimal control; J-spectral factorization; Linear systems; Polynomial; Polynomial equation; Polynomial matrix; Polynomial methods; Spectral factorization

Polynomial Spectral Factorization

As a mathematical tool, the spectral factorization was invented by Wiener in 1940s to find a frequency domain solution of optimal filtering problems. Since then, this technique has turned up numberless applications in system, network and communication theory, robust and optimal control, filtration, prediction and state reconstruction. Spectral factorization of scalar polynomials is naturally encountered in the area of single-input single-output systems.

In the context of continuous-time problems, real polynomials in a single complex variable s are typically used. For such a polynomial $p(s)$, its *adjoint* $p^*(s)$ is defined by

$$p^*(s) = p(-s), \tag{1}$$

which results in flipping all roots across the imaginary axis. If the polynomial is *symmetric,* then $p^*(s) = p(s)$ and its roots are symmetrically placed about the imaginary axis.

The *symmetric spectral factorization* problem is now formulated as follows: Given a symmetric polynomial $b(s)$,

$$b^*(s) = b(s), \tag{2}$$

that is also positive on the imaginary axis

$$b(i\omega) > 0 \quad \text{for all real } \omega, \tag{3}$$

find a real polynomial $x(s)$, which satisfies

$$x(s)x^*(s) = b(s) \tag{4}$$

as well as

$$x(s) \neq 0, \quad Res \geq 0. \tag{5}$$

Such an $x(s)$ is then called a *spectral factor* of $b(s)$. By (5), the spectral factor is a stable polynomial in the continuous-time (Hurwitz) sense.

Obviously, (4) is a quadratic equation in polynomials and its stable solution is the desired spectral factor.

Example 1 Given

$$b(s) = 4 + s^4 = (1 + j + s)(1 - j + s)$$
$$(1 + j - s)(1 - j - s),$$

(4) results in the spectral factor

$$x(s) = 2 + 2s + s^2 = (1 + j + s)(1 - j + s).$$

When the right-hand side polynomial $b(s)$ has some imaginary-axis roots, the problem formulated strictly as above becomes unsolvable since (3) does not hold and hence (5) cannot be fulfilled. A more relaxed formulation may then find its use requiring only $b(i\omega) \geq 0$ instead of (3) and $x(s) \neq 0$ only for $Res > 0$ instead of (5). Clearly, the imaginary-axis roots of $b(s)$ must then appear in $x(s)$ and $x^*(s)$ as well.

S

In the realm of discrete-time problems, one usually encounters *two-sided polynomial*s, which are polynomial-like objects (In fact, one can stay with standard one-sided polynomials (either in nonnegative or in nonpositive powers only), if every adjoint $p^*(z)$ is multiplied by proper power of z to create a one-sided polynomial $\bar{p}(z) = p^*(z)z^n$.) with positive and/or negative powers of a complex variable z, such as, for example, $p(z) = z^{-1} + 1 + 2z$. Here, the *adjoint* $p^*(z)$ stands simply for

$$p^*(z) = p(z^{-1}) \tag{6}$$

and the operation results in flipping all roots across the unit circle. If the two-sided polynomial is *symmetric*, then $p^*(z) = p(z)$ and its roots are symmetrically placed about the unit circle.

In its discrete-time version, the spectral factorization problem is stated as follows: Given a symmetric two-sided polynomial $b(z)$ that meets the conditions of symmetry

$$b^*(z) = b(z) \tag{7}$$

and positiveness (here on the unit circle)

$$b(e^{i\omega}) > 0 \quad \text{real } \omega, \ -\pi < \omega \leq \pi, \tag{8}$$

find a real polynomial $x(z)$ in nonnegative powers of z to satisfy

$$x(z)x^*(z) = b(z) \tag{9}$$

and

$$x(z) \neq 0, \quad |z| \geq 1. \tag{10}$$

By (10), the spectral factor is a stable polynomial in the discrete-time (Schur) sense.

Example 2 For

$$b(z) = 2z^{-2} + 6z^{-1} + 9 + 6z + 2z^2$$

$$= 2z^{-2}(z + 0.5 + 0.5j)(z + 0.5 - 0.5j)$$

$$(z + 1 + j)(z + 1 - j)$$

$$= 4(z + 0.5 + 0.5j)(z + 0.5 - 0.5j)$$

$$\times \ (z^{-1} + 0.5 + 0.5j)$$

$$(z^{-1} + 0.5 - 0.5j)$$

(9) yields

$$x(z) = 1 + 2z + 2z^2 = 2(z + 0.5 + 0.5j)$$

$$(z + 0.5 - 0.5j)$$

as the desired spectral factor.

When the right-hand side $b(z)$ possesses some roots on the unit circle, this problem turns out to be unsolvable as (8) fails. If necessary, a less restrictive formulation can then be applied replacing (8) by $b(e^{i\omega}) \geq 0$ and with $x(z) \neq 0$ only for $|z| > 1$ instead of (10). Clearly, the unit-circle roots of $b(z)$ must then appear both in $x(z)$ and $x^*(z)$.

When formulated as above, the spectral factorization problem is always solvable and its solution is unique up to the change of sign (if x is a solution, so is $-x$ and no other solutions exist).

Polynomial Matrix Spectral Factorization

Matrix version of the problem has been encountered since 1960s. In the world of continuous-time problems, real polynomial matrices in a single complex variable s are used. For such a real polynomial matrix $P(s)$, its *adjoint* $P^*(s)$ is defined as

$$P^*(s) = P^T(-s). \tag{11}$$

A polynomial matrix $P(s)$ is *symmetric* or, more precisely, *para-Hermitian*, if $P^*(s) = P(s)$. Needless to say, only square polynomial matrices can be symmetric.

The matrix spectral factorization problem is defined as follows: Given a symmetric polynomial matrix $B(s)$,

$$B^*(s) = B(s), \tag{12}$$

that is also positive definite on the imaginary axis

$$B(i\omega) > 0 \quad \text{for all real } \omega, \tag{13}$$

find a square real polynomial matrix $X(s)$, which satisfies

$$X(s)X^*(s) = B(s) \tag{14}$$

and has no zeros in the closed right half plain Re $s \geq 0$. Such an $X(s)$ is then called *a left spectral factor* of $B(s)$. A *right spectral factor* $Y(s)$ is defined similarly by replacing (14) with

$$Y^*(s)Y(s) = B(s). \tag{15}$$

Example 3 For a symmetric matrix

$$B(s) = \begin{bmatrix} 2 - s^2 & -2 - s \\ -2 + s & 4 - s^2 \end{bmatrix},$$

we have

$$X(s) = \begin{bmatrix} 1.4 + s & -0.2 \\ -1.2 & 1.6 + s \end{bmatrix}$$

as a left spectral factor and

$$Y(s) = \begin{bmatrix} 1 + s & 0 \\ -1 & 2 + s \end{bmatrix}$$

as a right one.

As in the scalar case, less restrictive definitions are sometimes used where the given right-hand side matrix $B(s)$ is only nonnegative definite on the imaginary axis and so the spectral factor is free of zeros in the open right half plain Re $s > 0$ only.

In the kingdom of discrete-time, *two-sided real polynomial* matrices $P(z)$ are used having in general entries with both positive and negative powers of the complex variable z. For such a matrix, its *adjoint* $P^*(z)$ is defined by

$$P^*(z) = P^T(z^{-1}). \tag{16}$$

Clearly, if $P(z)$ has only nonnegative powers of z, then $P^*(z)$ has only nonpositive powers of z and vice versa. A square two-sided polynomial matrix $P(z)$ is (*para-Hermitian*) *symmetric* if $P^*(z) = P(z)$.

Here is the discrete-time version of matrix spectral factorization problem. Given a two-sided polynomial matrix $B(z)$ that is symmetric

$$B^*(z) = B(z) \tag{17}$$

and positively definite on the unit circle

$$B(e^{i\omega}) > 0 \quad \text{real } \omega, \ -\pi < \omega \leq \pi, \tag{18}$$

find a real polynomial matrix $X(z)$ in nonnegative powers of z such that

$$X(z)X^*(z) = B(z) \tag{19}$$

and has no zeros on and outside of the unit circle. Such an $X(z)$ is then called *a left spectral factor* of $B(z)$. A *right* (The right and the left spectral factor are sometimes called the *factor* and the *cofactor*, respectively, but the terminology is not set at all.) *spectral factor* $Y(z)$ is defined similarly by replacing (19) with

$$Y^*(z)Y(z) = B(z) \tag{20}$$

Example 4 A symmetric two-sided polynomial matrix

$$B(z) = \begin{bmatrix} -2z^{-1} + 5 - 2z & 2z^{-1} - 1 \\ -1 + 2z & 2z^{-1} + 6 + 2z \end{bmatrix}$$

has a left spectral factor

$$X(z) \cong \begin{bmatrix} -1.1 + 1.9z & 0.55 \\ -0.8z & 0.95 + 2.1z \end{bmatrix}$$

and a right spectral factor

$$Y(z) = \begin{bmatrix} 2z - 1 & 1 \\ 0 & 1 + 2z \end{bmatrix}.$$

As before, less restrictive formulations are sometimes encountered where the given symmetric $B(z)$ is only nonnegatively definite on the unit circle and so the spectral factor must have no zeros only outside of the unit circle.

When formulated as above, the matrix spectral factorization problem is always solvable. The spectral factors are unique up to an orthogonal matrix multiple. That is, if X and X' are two left spectral factors of B, then

$$X' = UX \tag{21}$$

where U is a constant orthogonal matrix $UU^T = I$, while if Y and Y' are two right spectral factors of B, then

$$Y' = YV \qquad (22)$$

where V is a constant orthogonal matrix $V^T V = I$.

J-Spectral Factorization

In robust control, game theory and several other fields, the symmetric right-hand side in the matrix spectral factorization may have a general signature. With such a right-hand side, standard (positive or nonnegative definite) factorization becomes impossible. Here, a similar yet different J-spectral factorization takes its role.

In the context of continuous-time problems, the *J-spectral factorization problem* is formulated as follows. Given a symmetric polynomial matrix $B(s)$,

$$B^*(s) = B(s), \qquad (23)$$

find a square real polynomial matrix $X(s)$, which satisfies

$$X(s)JX^*(s) = B(s), \qquad (24)$$

where $X(s)$ has no zeros in the open right half plain Re s > 0 and J is a *signature matrix* of the form

$$J = \begin{bmatrix} I_1 & 0 & 0 \\ 0 & -I_2 & 0 \\ 0 & 0 & 0 \end{bmatrix} \qquad (25)$$

with I_1 and I_2 unit matrices of not necessarily the same dimensions. The bottom right block of zeros is often missing, yet it is considered here for generality. Such an $X(s)$ is called *a left J-spectral factor* of $B(s)$. A *right J-spectral factor* is defined by

$$Y^*(s)J Y(s) = B(s) \qquad (26)$$

instead of (24). For discrete-time problems, the J-spectral factorization is defined analogously.

The *J-spectral factorization* problem is quite general having standard (either positive or nonnegative) spectral factorization as a particular case. No necessary and sufficient existence conditions appear to be known for J-spectral factorization. A sufficient condition by Jakubovič (1970) states that the problem is solvable if the multiplicity of the zeros on the imaginary axis of each of the invariant polynomials of the right-hand side matrix is even. In particular, this condition is satisfied whenever det $B(s)$ has no zeros on the imaginary axis. In turn, the condition is violated if any of the invariant factors is not factorable by itself. An example of a nonfactorizable polynomial is $1 + s^2$.

The J-spectral factors are unique up to a J-orthogonal matrix multiple. That is, if X and X' are two left J-spectral factors of B, then

$$X' = UX, \qquad (27)$$

where U is a J-orthogonal matrix $UJU^T = J$, while if Y and Y' are two right J-spectral factors of B, then

$$Y' = YV, \qquad (28)$$

where V is a J-orthogonal matrix $V^T J V = J$.

Example 5 For

$$B(s) = \begin{bmatrix} 0 & 1-s \\ 1+s & 2-s^2 \end{bmatrix}$$

the signature matrix reads

$$J = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}$$

and the right J-spectral factor is

$$Y(s) = \begin{bmatrix} 1+s & \dfrac{3-s^2}{2} \\[2mm] 1+s & \dfrac{1-s^2}{2} \end{bmatrix}$$

Nonsymmetric Spectral Factorization

Spectral factorization can also be non-symmetric. For a scalar polynomial p (either in s or in z), this means to factor it directly as

$$p = p^+ p^- \qquad (29)$$

where p^+ is a stable factor of p (having all its roots either in the open left half plane or inside of the unit disc, depending on the variable type) while p^- is the "remaining" that is unstable factor. Eventual roots of p at the stability boundary either associate to p^+ or to p^-, depending on the application problem at hand.

For a matrix polynomial P, the non-symmetric factorization is naturally twofold: Either

$$P = P^+ P^- \qquad (30)$$

or

$$P = P^- P^+. \qquad (31)$$

For scalar polynomials, symmetric and non-symmetric spectral factors are closely related. Given p and having computed a symmetric factor x for pp^* as in (4) or (9) to get

$$x^* x = p^* p \qquad (32)$$

Then

$$p^+ = \gcd(p, x) \quad \text{and} \quad p^- = \gcd(p, x^*) \quad (33)$$

where *gcd* stands for a greatest common divisor. In reverse,

$$x = p^+ (p^-)^* \text{ and } x^* = p^- (p^+)^*. \qquad (34)$$

Unfortunately, no such relations exist for the matrix case.

Example 6 For example,

$$p(s) = 1 - s^2$$

factorizes into

$$p^+(s) = 1 + s, \quad p^-(s) = 1 - s$$

while for

$$P(s) = \begin{bmatrix} 1 + s & 0 \\ 1 + s^2 & 1 - s \end{bmatrix}$$

we have

$$P^-(s) = \begin{bmatrix} 1 & 1 \\ s & 1 \end{bmatrix}, P^+(s) = \begin{bmatrix} s & -1 \\ 1 & 1 \end{bmatrix}.$$

Algorithms and Software

Spectral factorization is a crucial step in the solution of various control, estimation, filtration, and other problems. It is no wonder that a variety of methods has been developed over the years for the computation of spectral factors. The most popular ones are briefly mentioned here. For details on particular algorithms, the reader is referred to the papers recommended for further reading.

Factor Extraction Method
If all roots of the right-hand side polynomial are known, the factorization becomes trivial. Just write the right-hand side as a product of first and second order factors and then collect the stable ones to create the stable factor. If the roots are not known, one can first enumerate them and then proceed as above. Somewhat surprisingly, a similar procedure can be used for the matrix case. To every zero, a proper matrix factor must be extracted. For further details, see Callier (1985) or Henrion and Sebek (2000).

Bauer's Algorithm
This procedure is an iterative scheme with linear rate of convergence. It relies on equivalence between the polynomial spectral factorization and the Cholesky factorization of a related infinite-dimensional Toeplitz matrix. For further details, see Youla and Kazanjian (1978).

Newton-Raphson Iterations
An iterative algorithm with quadratic convergence rate based on consecutive solutions of symmetric linear polynomial Diophantine equations. It is inspired by the classical Newton's method for finding a root of a function. To learn more, read Davis (1963), Ježek and Kučera (1985), Vostrý (1975).

Factorization via Riccati Equation
In state-space solution of various problems, an algebraic Riccati equation plays the role of spectral factorization. It is therefore not surprising that the spectral factor itself can directly be calculated by solution of a Riccati equation. For further info, see e.g. Šebek (1992).

FFT Algorithm

This is the most efficient and accurate procedure for factorization of scalar polynomials with very high degrees (in orders of hundreds or thousands). Such polynomials appear in some special problems of signal processing in advanced audio applications involving inversions of dynamics of loudspeakers or room acoustics. The algorithm is based on the fact that logarithm of a product (such as the spectral factorization equation) turns into a sum of logarithms of particular entries. For details, see Hromčík and Šebek (2007)

All the procedures above are either directly programmed or can be easily composed from the functions of *Polynomial Toolbox for Matlab*, which is a third-party Matlab toolbox for polynomials, polynomial matrices and their applications in systems, signals, and control. For more details on the toolbox, visit *www.polyx.com*.

Consequences and Comments

Polynomial and polynomial matrix spectral factorization is an important step when frequency domain (polynomial) methods are used for optimal and robust control, filtering, estimation, or prediction. Numerous particular examples can be found throughout this Encyclopedia as well as in the textbooks and papers recommended for further reading below.

Spectral factorization of rational functions and matrices is an equally important topic but it is omitted here due to lack of space. Inquiring readers are referred to the papers Oara and Varga (2000) and Zhong (2005).

Stability and Performance of Complex Systems Affected by Parametric Uncertainty

Boris Polyak and Pavel Shcherbakov
Institute of Control Science, Moscow, Russia

Abstract

Uncertainty is an inherent feature of all real-life complex systems. It can be described in different forms; we focus on the parametric description. The simplest results on stability of linear systems under parametric uncertainty are the Kharitonov theorem, edge theorem, and graphical tests. More advanced results include sufficient conditions for robust stability with matrix uncertainty, LMI tools, and randomized methods. Similar approaches are used for robust control synthesis, where performance issues are crucial.

Keywords

Edge theorem; Kharitonov theorem; Linear systems; Matrix; Parametric uncertainty and robustness; Quadratic stability; Randomized methods; Robust and optimal design; Robust stability; Tsypkin–Polyak plot

Introduction

Mathematical models for systems and control are often unsatisfactory due to the incompleteness of the parameter data. For instance, the ideas of off-line optimal control can only be applied to real systems if all the parameters, exogenous perturbations, state equations, etc. are known precisely. Moreover, feedback control also requires a detailed information which is not available in most cases. For example, to drive a car with four-wheel control, the controller should be aware of the total weight, location of the center of gravity, weather conditions, and highway properties as well as many other data which may not be known. In that respect, even such a relatively simple real-life system can be considered a *complex* one; in such circumstances, control under uncertainty is a highly important issue.

The focus in this article is on the *parametric uncertainty*; other types of uncertainty can be treated in more general models of robustness. This topic became particularly popular in the control community in the mid- to late 1980s of the previous century; at large, the results of this activity have been summarized in the monographs (Ackermann 1993; Barmish 1994; Bhattacharyya et al. 1995).

We start with problems of stability of polynomials with uncertain parameters and present the simplest robust stability results for this case together with the most important machinery. Next, we consider stability analysis for the matrix uncertainty; most of the results are just sufficient conditions. We present some useful tools for the analysis, such as the LMI technique and randomized methods. Robust control under parametric uncertainty is the next step; we briefly discuss several problem formulations for this case.

Stability of Linear Systems Subject to Parametric Uncertainty

Consider the closed-loop linear, time invariant continuous time state space system

$$\dot{x} = Ax, \qquad x(0) = x_0, \qquad (1)$$

where $x(t) \in \mathbb{R}^n$ is the state vector, x_0 is an arbitrary finite initial condition, and $A \in \mathbb{R}^{n \times n}$ is the state matrix. The system is stable (i.e., no matter what x_0 is, the solutions tend to zero as $t \to \infty$) if and only if all eigenvalues λ_i of the matrix A have negative real parts:

$$\mathrm{Re}\,\lambda_i < 0, \qquad i = 1, \dots, n, \qquad (2)$$

in which case, A is said to be a *Hurwitz* matrix. If it is known precisely, checking condition (2) is immediate. For instance, one might compute the characteristic polynomial

$$p(s) = \det(sI - A) = a_0 + a_1 s + \cdots +$$
$$a_{n-1}s^{n-1} + s^n \qquad (3)$$

of A (here, I is the identity matrix) and use any of the stability tests (e.g., the Routh algorithm, Routh–Hurwitz test, and graphical tests such as the Mikhailov plot or Hermite–Biehler theorem), see Gantmacher (2000). Alternatively, the eigenvalues can be directly computed using the currently available software, such as MATLAB.

However, things get complicated if the knowledge of the matrix A is incomplete; for instance,

it can depend on the (real) parameters $q = (q_1, \dots, q_m)$ which take arbitrary values within the given intervals:

$$A = A(q), \qquad \underline{q}_i \le q_i \le \overline{q}_i, \quad i = 1, \dots, m. \qquad (4)$$

In that case, we arrive at the *robust stability problem*; i.e., the goal is to check if condition (2) holds for *all matrices* in the family (4).

The two main components of any robust stability setup are the *feasible set* $\mathcal{Q} \subset \mathbb{R}^\ell$, in which the uncertain parameters are allowed to take their values (usually a ball in some norm; e.g., the box as in (4)), and the *uncertainty structure*, which defines the functional dependence of the coefficients on the uncertain parameters. Of the most interest are the affine and multiaffine dependence; typically, more general situations are hard to handle.

Simple Solutions

In some cases, the robust stability problem admits a simple solution. Perhaps the most striking example is the so-called Kharitonov theorem (Kharitonov 1978); also see Barmish (1994), where this seminal result is referred to as a *spark* because of its transparency and elegance.

Namely, consider the *interval polynomial family*

$$\mathcal{P} = \{p(s) = q_0 + q_1 s + \cdots + q_n s^n,$$
$$\underline{q}_i \le q_i \le \overline{q}_i, \quad i = 0, \dots, n\}, \quad (5)$$

where the coefficients q_i are allowed to take values in the respective intervals *independently of each other* and distinguish the following four elements in this family:

$$p_1(s) = \underline{a}_0 + \underline{q}_1 s + \overline{q}_2 s^2 + \overline{q}_3 s^3 + \dots$$
$$p_2(s) = \underline{q}_0 + \overline{q}_1 s + \overline{q}_2 s^2 + \underline{q}_3 s^3 + \dots$$
$$p_3(s) = \overline{q}_0 + \overline{q}_1 s + \underline{q}_2 s^2 + \underline{q}_3 s^3 + \dots$$
$$p_4(s) = \overline{q}_0 + \underline{q}_1 s + \underline{q}_2 s^2 + \overline{q}_3 s^3 + \dots$$

By the Kharitonov theorem, the interval family (5) is robustly stable (i.e., all polynomials

in (5) are Hurwitz having all roots with negative real parts) if and only if the *four Kharitonov polynomials*, p_1, p_2, p_3, and p_4, are Hurwitz.

A simple and transparent proof of this result can be obtained using the *value set concept* (Zadeh and Desoer 1963) and the *zero exclusion* principle (Frazer and Duncan 1929), the two general tools which are in the basis of many results in the area of robust stability. We illustrate these concepts via robust stability of polynomials.

Given the uncertain polynomial family

$$\mathcal{P}(s, Q) = \{p(s, q), \quad q \in \mathcal{Q}\},$$

the set

$$\mathcal{V}(\omega) = \{p(j\omega, q): \ \omega \geq 0, \ q \in \mathcal{Q}\}$$

is referred to as the *value set*, which is, by definition, the set on the complex plane obtained by fixing the argument s to be $j\omega$ for a certain value of ω and letting the uncertain parameter vector q sweep the feasible domain.

The zero exclusion principle states that, under certain regularity requirements, the uncertain polynomial family is robustly stable if and only if it contains a stable element and the following condition holds:

$$0 \notin \mathcal{V}(\omega) \quad \forall \, \omega \geq 0. \tag{6}$$

To use this machinery, one has to be able to compute efficiently the value set and check condition (6). For the interval family (5), the value set can be shown to be the rectangle with coaxial edges and the vertices being the values of the four Kharitonov polynomials; see Fig. 1.

Being an extremely propelling result, the Kharitonov theorem is not free of drawbacks. First of all, it is not capable of determining the maximal lengths of the uncertainty intervals that retain the robust stability. This relates to an important notion of *robust stability margin*; for simplicity, we define this quantity for the case of the interval family (5). Namely, introduce the *nominal polynomial* $p_0(s)$ with coefficients

$$q_i^0 = (\overline{q}_i + \underline{q}_i)/2,$$
Stability and Performance of Complex Systems Affected by Parametric Uncertainty, Fig. 1 The Kharitonov rectangular value set

and the *scaling factors*

$$\alpha_i = (\overline{q}_i - \underline{q}_i)/2$$

for the deviations of the coefficients. Then the robust stability margin $r_{\max}$ is defined as follows:

$$r_{\max} = \sup\{r: \ p(s, q) \ (5) \text{ is stable } \forall \, q_i:$$
$$|q_i - q_i^0| \leq r\alpha_i, \quad i = 1, \ldots, n\}. \tag{7}$$

Anther drawback of the Kharitonov result is its inapplicability to the discrete-time case (Schur stability of polynomials).
A more flexible graphical test for robust stability uses the so-called Tsypkin–Polyak plot (Tsypkin and Polyak 1991), which is defined as the parametric curve on the complex plane:

$$z(\omega) = x(\omega) + jy(\omega), \ j = \sqrt{-1}; \ 0 \leq \omega < \infty,$$

where

$$x(\omega) = \frac{q_0^0 - q_2^0\omega^2 + \ldots}{\alpha_0 + \alpha_2\omega^2 + \ldots},$$

$$y(\omega) = \frac{q_1^0 - q_3^0\omega^2 + \ldots}{\alpha_1 + \alpha_3\omega^2 + \ldots}. \tag{8}$$

Then, by the Tsypkin–Polyak criterion, the polynomial family (5) is robustly stable if and only if the following conditions hold: (i) $q_0^0 > \alpha_0$,

Stability and Performance of Complex Systems Affected by Parametric Uncertainty, Fig. 2 The Tsypkin–Polyak plot

$q_n^0 > \alpha_n$, and (ii) as ω changes zero to infinity, the curve $z(\omega)$ goes consecutively through n quadrants in the counterclockwise direction and does not intersect the unit square with the vertices $(\pm 1, \pm j)$.

Unlike the Kharitonov theorem, with this test, the robust stability margin of family (5) can be determined as the size of the maximal square inscribed in the curve $z(\omega)$; see Fig. 2. Moreover, with minor modifications, this test applies to *dependent uncertainty structures* where the coefficient vector $q = (q_0, \ldots, q_n)^\top$ is confined to a ball in ℓ_p-norm, not to a *box* as in (5).

On top of that, the Tsypkin–Polyak plot can be built for discrete-time systems which do not admit any counterparts of the Kharitonov theorem.

It is fair to say that interval polynomial families is an idealization, since the coefficients of the characteristic polynomial can hardly be thought of as the physical parameters of the real-world system. As a step towards more realistic formulations, consider the *affine polynomial family* of the form

$$p(s) = p_0(s) + \sum_{i=1}^{m} q_i \, p_i(s), \quad |q_i| \leq 1,$$
$$i = 1, \ldots, m, \quad (9)$$

where p_i are the given polynomials and the q_is are the uncertain parameters (clearly, they can

be scaled to take values in the segment $[-1, 1]$). The famous *edge theorem* (Bartlett et al. 1988) claims that checking the robust stability of such a family is equivalent to checking the *edges* of the uncertainty box, i.e., the points $q \in \mathbb{R}^m$ with all but one components being fixed to ± 1, while the "free" coordinate varies in $[-1, 1]$.

Complex Solutions

Obviously, the affine model (9) covers just a small part of problems with parametric uncertainty. Closed-form solutions cannot be obtained in the general case; however, many important classes of systems can be analyzed efficiently.

Thus, in the engineering practice, *block diagram description* of systems is often more convenient than differential equations of the form (1). The blocks are associated with typical elements such as amplifiers, integrators, lag elements, and oscillators, which are connected in a certain circuit. In this case, transfer functions are the most adequate tool for dealing with such systems. For instance, the transfer function of the lag element is given by

$$W(s) = 1/(Ts + 1),$$

where the scalar T is the *time constant* of the element. In terms of differential equations, this means that the input $u(t)$ of a block and its output $x(t)$ satisfy the equation $T\dot{x} + x = u$.

Assume now we have a set of m cascade connected elements with uncertain time constants

$$\underline{T}_i \leq T_i \leq \overline{T}_i, \quad i = 1, \ldots, m, \quad (10)$$

with known lower and upper bounds. The characteristic polynomial of such a connection embraced by the feedback with *gain k* is known to have the form

$$p(s) = k + (1 + T_1 s) \cdots (1 + T_m s). \quad (11)$$

Hence, the robust stability problem reduces to checking if all polynomials (11) with constraints (10) are Hurwitz. Note that the coefficients of such a polynomial depend *multilinearly* on the uncertain parameters T_i

(cf. linear dependence in (9)), making the problem much more complicated.

The solution of the problem above was obtained in Kiselev et al. (1997) for many important special cases; the closely related problem of finding the "critical gain" (the maximal value of k retaining the robust stability) was also addressed.

Using the similar technique, closed-form solutions can be obtained for a number of similar problems such as robust sector stability, robust stability of distributed systems, robust D-decomposition, to name just a few.

Difficult Problems: Possible Approaches

In spite of the apparent progress obtained in the area of parametric robustness, the list of unsolved problems is still quite large. Moreover, some of the formulations were shown to be NP-hard, making it hard to believe that any efficient solution methods will ever be found.

One of such fundamental problems is robust stability of the *interval matrix*. Specifically, assume that the entries a_{ij} of the matrix A in (1) are interval numbers

$$\underline{a}_{ij} \le a_{ij} \le \overline{a}_{ij}, \qquad i, j = 1, \ldots, n;$$

the problem is to check if the interval matrix is robustly stable, i.e., if the eigenvalues of all matrices in this family have negative real parts. Numerous attempts to prove a Kharitonov-like theorem for matrices have failed, and the results by Nemirovskii (1994) on NP-hardness showed that these generalizations are not possible. It was also shown that the edge theorem for matrix families is not valid. The other NP-hard problems in robustness include the analysis of systems with interval delays, parallel connection of uncertain blocks, problem (11)–(10) with nested segments $[\underline{T}_i, \overline{T}_i]$, and others.

However, a change in the statement of the problem often allows for simple and elegant solutions. We mention three fruitful reformulations.

In the first approach, the uncertain parameters are assumed to have random rather than deterministic nature; for instance, they are assumed to be uniformly distributed over the respective intervals of uncertainty. We next specify an acceptable

tolerance ε, say $\varepsilon = 0.01$, and check if the resulting random family of polynomials is stable with probability no less than $(1 - \varepsilon)$; see Tempo et al. (2013) for a comprehensive exposition of such a *randomized approach to robustness*.

In many of the NP-hard robustness problems, such a reformulation often leads to exact or approximate solutions. Moreover, the randomized approach has several attractive properties even in the situations where the deterministic solution is available. Indeed, the deterministic statements of robustness problems are minimax; hence, the answer is dictated by the "worst" element in the family, whereas these critical values of the uncertain parameters are rather unlikely to occur. Therefore, by neglecting a small risk of violation of the stability, the admissible domains of variation of the parameters may be considerably extended. This effect is known as the *probabilistic enhancement of robustness margins*; it is particularly tangible for the large number of the parameters. Another attractive property of the randomized approach is its low computational complexity which only slowly grows with increase of the number of uncertain parameters.

To illustrate, let us turn back to problem (11)–(10) and use the value set approach. In the considered problem, this set can be efficiently built.

Assume now that the parameters T_i are independent random variables uniformly distributed over the respective segments (10) and consider the random variable

$$\eta = \eta(\omega) = \log(p(j\omega) - k) = \sum_{i=1}^{m} \log(1 + j\omega T_i). \tag{12}$$

The right-hand side of the last relation is the sum of independent complex-valued random variables; for m large, its behavior obeys the central limit theorem, so that the probability that η belongs to the respective *confident ellipse* $\mathcal{E} = \mathcal{E}(\omega)$ is close to unity. In other words, we have

$$p(j\omega) \approx k + e^{\mathcal{E}} \doteq \mathcal{G}(\omega),$$

and the set $\mathcal{G}(\omega)$ is referred to as a *probabilistic predictor* of the value set $\mathcal{V}(\omega)$; it is the shifted

set of points of the form $e^z, z \in \mathcal{E} \subset \mathbb{C}$. The predictor $\mathcal{G}(\omega)$ constitutes a small portion of the deterministic value set $\mathcal{V}(\omega)$, yielding the probabilistic enhancement of the robustness margin.

Note also that the computation of $\mathcal{E}$ and $e^{\mathcal{E}}$ is nearly trivial and, in contrast to the construction of the true value set $\mathcal{V}$, the complexity does not grow with increase of m.

The second approach to solving "hard" problems in robust stability relates to the notion of *superstability* (Polyak and Shcherbakov 2002). The matrix A of system (1) (and the system itself) is said to be superstable, if its entries a_{ij}, $i, j = 1, \ldots, n$, satisfy the relations

$$a_{ii} < 0, \qquad \min_i(-a_{ii} - \sum_{j \neq i} |a_{ij}|) = \sigma > 0.$$

The following estimate holds for the solutions of the superstable system (1):

$$\|x(t)\|_\infty \leq \|x(0)\|_\infty e^{-\sigma t},$$

i.e., it is stable, and the (nonsmooth) function $\|x\|_\infty$ is a Lyapunov function for the system. Since the condition of superstability is formulated in terms of linear inequalities on the entries of A, checking robust superstability of affine (and in particular, interval) matrix families is immediate. Similar situation holds for so-called positive systems.

The third approach to robustness analysis relates to *quadratic stability* (Leitmann 1979; Boyd et al. 1994). Namely, a family of systems is said to be *robustly quadratically stable* if it possesses a common quadratic Lyapunov function $V(x) = x^\top P x$ with positive definite matrix P. In other words, an uncertain family of matrices $A(q), q \in \mathcal{Q}$ has to satisfy the following set of the matrix Lyapunov-type inequalities:

$$A(q)P + PA(q)^\top \prec 0, \quad q \in \mathcal{Q}, \quad P \succ 0, \tag{13}$$

where the symbols $\prec, \succ$ stand for the sign-definiteness of a matrix.

The inequality above is referred to as a *linear matrix inequality* (LMI), (Boyd et al. 1994); there exist both efficient numerical methods for solving

such inequalities (*interior point methods*) and various software, e.g., MATLAB. This approach can be directly applied at least in the following two cases: (i) the set $\mathcal{Q}$ contains a finite number of points and (ii) $\mathcal{Q}$ is a polyhedron and the dependence $A(q)$ is affine. In the general setup or in the high-dimensional problems, randomized methods can be employed.

Finding the *quadratic robust stability margin* (by analogy with the stability margin, this is the maximum span of the feasible set $\mathcal{Q}$ that allows for the existence of the common Lyapunov function) in this problem is also possible; it reduces to the minimization of a linear function over the solutions of a similar LMI.

Note that the approaches based on superstability and quadratic stability provide only sufficient conditions for robustness.

Robust Control

So far, of our primary interest was in assessing the robust stability of a closed-loop system with synthesized linear feedback. A more important problem is to *design* a controller that makes the closed-loop system robustly stable and guarantees certain *robust performance* of the system.

Robust Stabilization
Let the linear system

$$\dot{x} = A(q)x + Bu$$

depend on the vector $q \in \mathcal{Q}$ of uncertain parameters. In the simplest form, the problem of *robust stabilization* consists in finding the linear static state feedback

$$u = Kx$$

that guarantees the robust stability of the closed-loop system. Alternatively, static or dynamic *output* robustly stabilizing controllers can be considered in the situations where only the linear output $y = Cx$ of the system is available, but not the complete state vector x.

If the number of controller parameters to be tuned is small (which is the case for PI or PID controllers), then the design can be accomplished using the *D-decomposition technique*.

In the general formulation, the problem of robust design is complicated; it can, however, be addressed with the use of randomized methods (Tempo et al. 2013). Other plausible approaches include superstability and quadratic stability; respectively, the problem reduces to solving linear programs or linear matrix inequalities in the coefficients of the controller.

Robust Performance

Needless to say, the robust stabilization problem is not the only one in the area of optimal control. As a rule, a certain cost function is always involved (say, integral quadratic), and its desired value should be guaranteed for all admissible values of the uncertain parameters. Moreover, robust stability is a necessary condition for such a guaranteed estimate to exist. This sort of problems can often be cast in the form of LMIs which must be satisfied for all admissible values of the parameters. Such robust LMIs can be solved either directly or using various randomized techniques presented in Tempo et al. (2013).

Conclusions

In spite of the considerable progress attained in the parametric robustness of complex systems, this topic is still a vivid and active research area. To date, randomization, superstability, and quadratic stability present the most efficient and diverse tools for the analysis and design of systems affected by parametric uncertainty.

Stability Theory for Hybrid Dynamical Systems

Andrew R. Teel
Electrical and Computer Engineering
Department, University of California, Santa
Barbara, CA, USA

Abstract

This entry provides a short introduction to modeling of hybrid dynamical systems and then focuses on stability theory for these systems. It provides

definitions of asymptotic stability, basin of attraction, and uniform asymptotic stability for a compact set. It points out mild assumptions under which different characterizations of asymptotic stability are equivalent, as well as when an asymptotically stable compact set exists. It also summarizes necessary and sufficient conditions for asymptotic stability in terms of Lyapunov functions.

Keywords

Asymptotic stability; Basin of attraction; Hybrid system; Lyapunov function

Introduction

A hybrid dynamical system combines continuous change and instantaneous change. Instantaneous change is the only type of change available for variables like counters, switches, and logic variables. Instantaneous change may also be a good approximation of what occurs to velocities in mechanical systems at the time of an impact with a wall, floor, or some other rigid body. At other times, velocities evolve continuously. Continuous change is also natural for position variables, continuous timers, and voltages and currents. For mathematical convenience, it is typical in the analysis of hybrid dynamical systems to embed all of these variables into a Euclidean space, with the understanding that many points in the state space will never be reached. For example, a logic variable that naturally takes values in the set {off, on} is typically embedded in the real number line where its two distinct values are associated with two distinct numbers, the only numbers that this variable will visit during its evolution.

A finite-dimensional dynamical system that exhibits continuous change exclusively is typically modeled by an ordinary differential equation, or sometimes a more flexible differential inclusion. A system that exhibits purely instantaneous change is typically modeled by a difference equation or inclusion. Consequently, a hybrid dynamical system combines a differential equation or inclusion with a difference equation

or inclusion. A big part of the modeling effort for hybrid systems is directed at determining which type of evolution should be allowed at each point in the state space. To this end, subsets of the state space are specified where each type of behavior is allowed, like in the description of the heating system given above.

Though the behavior of a hybrid dynamical system can be quite complex and nonconventional, it is still reasonable to ask the same stability questions for them that might be asked about classical differential or difference equations. Moreover, the same stability analysis tools that are used for classical systems are also quite useful for hybrid dynamical systems. The emphasis of this entry is on basic stability theory for hybrid dynamical systems, focusing on definitions and tools that also apply to classical systems.

Mathematical Modeling

System Data
A hybrid dynamical system with state x belonging to a Euclidean space $\mathbb{R}^n$ combines a differential equation or inclusion, written formally as $\dot{x} = f(x)$ or $\dot{x} \in F(x)$, with a difference equation or inclusion $x^+ = g(x)$ or $x^+ \in G(x)$, where $\dot{x}$ indicates the time derivative and x^+ indicates the value after an instantaneous change. The mapping f or F is called the *flow map*, while the mapping g or G is called the *jump map*. A complete model also specifies where in the state space continuous evolution is allowed and where instantaneous change is allowed. The set where continuous evolution is allowed is called the *flow set* and is denoted C, whereas the set where instantaneous change is allowed is called the *jump set* and is denoted D. The overall model, using inclusions for generality, is written formally as

$$x \in C \qquad \dot{x} \in F(x) \tag{1a}$$

$$x \in D \qquad x^+ \in G(x). \tag{1b}$$

Solutions
It is natural for solutions of (1) to be functions of two different types of time: a variable t that keeps track of the amount of ordinary time that has

elapsed and a variable j that counts the number of jumps. There is a special structure to the types of domains that are allowed. A *compact hybrid time domain* is a set $E \subset \mathbb{R}_{\geq 0} \times \mathbb{Z}_{\geq 0}$, that is, a subset of the product of the nonnegative real numbers and the nonnegative integers, of the form

$$E = \bigcup_{i=0}^{J} ([t_i, t_{i+1}] \times \{i\})$$

for some $J \in \mathbb{Z}_{\geq 0}$ and some sequence of non-decreasing times $0 = t_0 \leq t_1 \leq \cdots \leq t_{J+1}$. It is possible for several of these times to be the same, which would correspond to more than one jump at the given time. A *hybrid time domain* is a set $E \subset \mathbb{R}_{\geq 0} \times \mathbb{Z}_{\geq 0}$ such that for each $(T, J) \in E$, the set $E \cap ([0, T] \times \{0, \ldots, J\})$ is a compact hybrid time domain. In contrast to a compact hybrid time domain, a hybrid time domain may have an infinite number of intervals, or it may have a finite number of intervals with the last one being unbounded or of the form $[t_J, t_{J+1})$; that is, it may be open on the right. A *hybrid arc* is a function x, defined on a hybrid time domain, such that $t \mapsto x(t, j)$ is locally absolutely continuous for each j; in particular, $t \mapsto x(t, j)$ is differentiable for almost every t where it is defined, and this mapping is the integral of its derivative. The notation "dom x" denotes the domain of x. Finally, a hybrid arc is a *solution* of (1) if the following two properties are satisfied:

1. For $\varepsilon > 0$, $(s, j), (s + \varepsilon, j) \in \text{dom } x$ implies that $x(t, j) \in C$ and $\dot{x}(t, j) \in F(x(t, j))$ for almost all $t \in [s, s + \varepsilon]$.
2. $(t, j), (t, j + 1) \in \text{dom } x$ implies that $x(t, j) \in D$ and $x(t, j + 1) \in G(x(t, j))$.

For a hybrid system with no flow dynamics, each solution has a time domain of the form $\{0\} \times \{0, \ldots, J\}$ for some $J \in \mathbb{Z}_{\geq 0}$ or $\{0\} \times \mathbb{Z}_{\geq 0}$. For a hybrid system with no jump dynamics, each solution has a time domain of the form $[0, \infty) \times \{0\}$, $[0, T] \times \{0\}$, or $[0, T) \times \{0\}$ for some $T \geq 0$. No assumptions are made in this entry to guarantee existence of nontrivial solutions since stability theory does not hinge on existence of solutions; rather, it simply makes statements about the behavior of solutions when they exist. To ensure robustness of various stability properties, the following basic regularity assumptions are usually imposed.

Assumption 1 The data (C, F, D, G) satisfy the following conditions:
1. The sets C and D are closed.
2. The set-valued mapping F is outer semi-continuous, locally bounded, and $F(x)$ is nonempty and convex for each $x \in C$.
3. The set-valued mapping G is outer semi-continuous, locally bounded, and $G(x)$ is nonempty for each $x \in D$.

To elaborate further, a set-valued mapping, like F, is said to be *outer semicontinuous* if for each convergent sequence $\{(x_i, y_i)\}_{i=0}^{\infty}$ that satisfies $y_i \in F(x_i)$ for all $i \in \mathbb{Z}_{\geq 0}$, its limit, denoted (x, y), satisfies $y \in F(x)$. It is said to be *locally bounded* if for each bounded set $K_1 \subset \mathbb{R}^n$ there exists a bounded set $K_2 \subset \mathbb{R}^n$ such that, for every $x \in K_1$, every $y \in F(x)$ belongs to K_2; the latter condition is sometimes written $F(K_1) \subset K_2$. If C is closed, f is a function $f : C \to \mathbb{R}^n$ that is continuous, and F is a set-valued mapping that has the single value $f(x)$ for each $x \in C$ and is empty for $x \notin C$, then F is outer semicontinuous, locally bounded, and $F(x)$ is nonempty and convex for each $x \in C$.

Stability Theory

Definitions and Relationships

Given a dynamical system, predicting or controlling the system's long-term behavior is of primary importance. A system's long-term behavior may be more complicated than just converging to an equilibrium point. This fact motivates studying stability of and convergence to a set of points. For simplicity, this entry focuses on stability of sets that are *compact*, that is, they are closed and bounded. A variety of stability concepts are defined below. Each of these concepts applies to continuous-time or discrete-time systems as readily as to hybrid systems.

A compact set $\mathcal{A} \subset \mathbb{R}^n$ is said to be *Lyapunov stable* for (1) if for each $\varepsilon > 0$ there exists $\delta > 0$ such that for every solution of (1), $x(0, 0) \in \mathcal{A} + \delta \mathbb{B}$ implies $x(t, j) \in \mathcal{A} + \varepsilon \mathbb{B}$ for all $(t, j) \in$

dom x, where $\mathcal{A} + \delta\mathbb{B}$ indicates the set of points whose distance to the set $\mathcal{A}$ is less than or equal to δ. In order for a compact set to be Lyapunov stable for (1), it must be *forward invariant* for (1), that is, each solution of (1) with $x(0,0) \in \mathcal{A}$ satisfies $x(t,j) \in \mathcal{A}$ for all $(t,j) \in$ dom x. However, forward invariance does not necessarily imply Lyapunov stability.

For a compact set $\mathcal{A} \subset \mathbb{R}^n$, its *basin of attraction* for (1), denoted $\mathcal{B}_\mathcal{A}$, is the set of points from which each solution to (1) is bounded and each solution to (1) having an unbounded time domain converges to $\mathcal{A}$, the latter being written mathematically as $\lim_{t+j \to \infty} |x(t,j)|_\mathcal{A} = 0$ where $|x(t,j)|_\mathcal{A}$ denotes the distance of $x(t,j)$ to the set $\mathcal{A}$. Each point that does not belong to $C \cup D$ belongs to $\mathcal{B}_\mathcal{A}$ since there are no solutions from such points. A compact set $\mathcal{A}$ is said to be *attractive* for (1) if its basin of attraction contains a neighborhood of itself, that is, there exists $\varepsilon > 0$ such that $\mathcal{A} + \varepsilon\mathbb{B} \subset \mathcal{B}_\mathcal{A}$. A compact set $\mathcal{A}$ is said to be *globally attractive* if $\mathcal{B}_\mathcal{A} = \mathbb{R}^n$.

A compact set is said to be *asymptotically stable* for (1) if it is Lyapunov stable and attractive for (1). A compact set is said to be *globally asymptotically stable* for (1) if it asymptotically stable for (1) and $\mathcal{B}_\mathcal{A} = \mathbb{R}^n$. It is useful to know that the basin of attraction for an asymptotically stable set is always open.

Theorem 1 *Under Assumption 1, if a compact set is asymptotically stable for (1), then its basin of attraction is an open set.*

A compact set $\mathcal{A} \subset \mathbb{R}^n$ is said to be *uniformly attractive* for (1) if it is attractive for (1) and for each compact set $K \subset \mathcal{B}_\mathcal{A}$ and each $\delta > 0$ there exists $T > 0$ such that for every solution x of (1), $x(0,0) \in K$ and $t + j \geq T$ imply $x(t,j) \in \mathcal{A} + \delta\mathbb{B}$. A compact set is said to be *uniformly globally attractive* for (1) if it is globally attractive and uniformly attractive for (1). Uniform attractivity goes beyond attractivity by asking that the amount of time it takes each solution to get close to $\mathcal{A}$ is uniformly bounded over initial conditions in compact subsets of the basin of attraction.

A compact set $\mathcal{A} \subset \mathbb{R}^n$ is said to be *Lagrange stable* relative to an open set $O \supset \mathcal{A}$ for (1) if for each compact set $K_1 \subset O$ there exists a compact set $K_2 \subset O$ such that for every solution of (1), $x(0,0) \in K_1$ implies $x(t,j) \in K_2$ for all $(t,j) \in$ dom x. In Lagrange stability for the case $O = \mathbb{R}^n$, a bound on the initial conditions is given and a bound on the ensuing solutions must be found; this is in contrast to Lyapunov stability where a bound on the solutions is given and a bound on the initial conditions must be found.

A compact set is said to be *uniformly asymptotically stable* for (1) if it is Lyapunov stable, attractive, Lagrange stable relative to its basin of attraction, and uniformly attractive for (1). A compact set is said to be *uniformly globally asymptotically stable* for (1) if it is uniformly asymptotically stable for (1) and $\mathcal{B}_\mathcal{A} = \mathbb{R}^n$. There is no difference between asymptotic stability and uniform asymptotic stability under Assumption 1.

Theorem 2 *Under Assumption 1, a compact set is uniformly asymptotically stable for (1) if and only if it is locally asymptotically stable for (1).*

As noted earlier, forward invariance does not imply Lyapunov stability. However, when coupled with uniform attractivity, Lyapunov stability ensues.

Theorem 3 *Under Assumption 1, a compact set is uniformly asymptotically stable for (1) if and only if it is forward invariant and uniformly attractive for (1).*

Asymptotic stability can be converted to global asymptotic stability by shrinking the flow and jump sets to be compact subsets of the basin of attraction. However, global asymptotic stability of a compact set $\mathcal{A}$ for $x \in C, \dot{x} = f(x)$ for each compact set C does not necessarily imply global asymptotic stability of $\mathcal{A}$ for $\dot{x} = f(x)$.

In some situations it is easier to assert the existence of a compact asymptotically stable set than it is to find one explicitly. In this direction, given a set $X \subset \mathbb{R}^n$, consider the set of points z with the property that there exist a sequence of solutions $\{x_i\}_{i=0}^\infty$ to (1) with initial conditions in X and a sequence of times $\{(t_i, j_i)\}_{i=0}^\infty$ with $(t_i, j_i) \in$ dom x_i for each $i \in \mathbb{Z}_{\geq 0}$ such that $z = \lim_{i \to \infty} x_i(t_i, j_i)$. This set of points is called the ω-limit set of X for (1) and is denoted $\Omega(X)$.

Theorem 4 *Let Assumption 1 hold. For the system (1), if X is compact and $\Omega(X)$ is nonempty and contained in the interior of X (i.e., there exists $\varepsilon > 0$ such that $\Omega(X) + \varepsilon\mathbb{B} \subset X$), then the set $\Omega(X)$ is compact and uniformly asymptotically stable with basin of attraction containing X and equal to the basin of attraction for X.*

Robustness

A given model (C, F, D, G) may have some mismatch with a physical process that it aims to describe. One way to capture some of this mismatch is to consider the behavior of solutions to a system with inflated data $(C_\delta, F_\delta, D_\delta, G_\delta)$, $\delta \geq 0$, defined as follows:

$$C_\delta := \{x \in \mathbb{R}^n : (x + \delta\mathbb{B}) \cap C \neq \varnothing\} \quad (2a)$$

$$F_\delta(x) := \overline{\mathrm{co}}F((x + \delta\mathbb{B}) \cap C) + \delta\mathbb{B} \quad (2b)$$

$$D_\delta := \{x \in \mathbb{R}^n : (x + \delta\mathbb{B}) \cap D \neq \varnothing\} \quad (2c)$$

$$G_\delta := G((x + \delta\mathbb{B}) \cap D) + \delta\mathbb{B}. \quad (2d)$$

The notation $x + \delta\mathbb{B}$ indicates a closed ball of radius δ centered at the point x. Evaluating a set-valued mapping at a set of points means to collect all vectors that belong to the set-valued mapping at any point in the set that serves as the argument of the set-valued mapping. The notation "$\overline{\mathrm{co}}F((x + \delta\mathbb{B}) \cap C)$" indicates the closed, convex hull of the set $\{f \in \mathbb{R}^n : f \in F(z), z \in (x + \delta\mathbb{B}) \cap C\}$. Note that $(C_0, F_0, D_0, G_0) = (C, F, D, G)$. More generally, the components of (C, F, D, G) are contained in $(C_\delta, F_\delta, D_\delta, G_\delta)$. The inflation data in (2) satisfy the regularity properties of Assumption 1 when (C, F, D, G) do.

Proposition 1 *If the data (C, F, D, G) satisfy Assumption 1 then, for each $\delta > 0$, the inflated data $(C_\delta, F_\delta, D_\delta, G_\delta)$ satisfy Assumption 1.*

From the point of view of asymptotic stability, the behavior of solutions to $(C_\delta, F_\delta, D_\delta, G_\delta)$ for $\delta > 0$ small is not too different from those of (C, F, D, G).

Theorem 1 *Under Assumption 1, if $\mathcal{A}$ is asymptotically stable with basin of attraction $\mathcal{B}_\mathcal{A}$ for the hybrid system with data (C, F, D, G), then for*

each $\varepsilon > 0$ and each compact set K satisfying $K \subset \mathcal{B}_\mathcal{A}$, there exist $\delta > 0$ and a compact set $\mathcal{A}_\delta \subset \mathcal{A} + \varepsilon\mathbb{B}$ that is asymptotically stable with $K \subset \mathcal{B}_{\mathcal{A}_\delta}$ for $(C_\delta, F_\delta, D_\delta, G_\delta)$.

The robustness result of Theorem 1 has several consequences beyond the observations in the preceding examples. One of the consequences is the following reduction principle.

Theorem 2 *Under Assumption 1, if $\mathcal{A}_1$ is asymptotically stable with basin of attraction $\mathcal{B}_{\mathcal{A}_1}$ for the hybrid system with data (C, F, D, G) and the compact set $\mathcal{A}_2 \subset \mathcal{A}_1$ is globally asymptotically stable for the hybrid system with data $(C \cap \mathcal{A}_1, F, C \cap \mathcal{A}_2, G)$, then the compact set $\mathcal{A}_2$ is asymptotically stable with basin of attraction $\mathcal{B}_{\mathcal{A}_1}$ for the hybrid system with data (C, F, D, G).*

Lyapunov Functions

Arguably the most common method for establishing asymptotic stability is known as *Lyapunov's method* and uses a Lyapunov function. A function $V : \mathbb{R}^n \to \mathbb{R}_{\geq 0}$ is a *Lyapunov function candidate* for (1) if it is continuously differentiable on an open neighborhood of the flow set C, it is defined for all $x \in C \cup D \cup G(D)$ (dom V denotes the set of points where it is defined), and it is continuous on its domain. Some of these conditions can be relaxed but are imposed in this entry to keep the discussion simple. Given a compact set $\mathcal{A}$ and an open set O satisfying $\mathcal{A} \subset O \subset \mathbb{R}^n$, a Lyapunov function candidate for (1) is called a *Lyapunov function for $(\mathcal{A}, O)$* if:

(L1) For $x \in (C \cup D \cup G(D)) \cap O$, $V(x) = 0$ if and only if $x \in \mathcal{A}$.

(L2) For each $x \in C \cap O$ and $f \in F(x)$, $\langle \nabla V(x), f \rangle \leq 0$.

(L3) For each $x \in D \cap O$ and $g \in G(x)$, $V(g) - V(x) \leq 0$.

A Lyapunov function for $(\mathcal{A}, O)$ is called a *proper Lyapunov function for $(\mathcal{A}, O)$* if, in addition,

(L4) $\lim_{i \to \infty} V(x_i) = \infty$ when the sequence $\{x_i\}_{i=0}^\infty$, satisfying $x_i \in (C \cup D \cup G(D)) \cap O$ for all $i \in \mathbb{Z}_{\geq 0}$, is unbounded or approaches the boundary of O.

The next result does not use Assumption 1, though the rest of the results in this entry do.

Theorem 3 *Let $\mathcal{A} \subset O \subset \mathbb{R}^n$ with $\mathcal{A}$ compact and O open. If there exists a Lyapunov function for $(\mathcal{A}, O)$, then $\mathcal{A}$ is Lyapunov stable for (1). If there exists a proper Lyapunov function for $(\mathcal{A}, O)$ then $\mathcal{A}$ is also Lagrange stable with respect to O for (1).*

We can also conclude asymptotic stability from a Lyapunov function when it is known that there are no complete solutions along which the Lyapunov function is equal to a positive constant.

Theorem 4 *Let $\mathcal{A} \subset O \subset \mathbb{R}^n$ with $\mathcal{A}$ compact and O open. Under Assumption 1, if there exists a Lyapunov function for $(\mathcal{A}, O)$ and there is no solution x of (1) starting in $O \setminus \mathcal{A}$ that has an unbounded time domain and satisfies $V(x(t, j)) = V(x(0, 0))$ for all $(t, j) \in \mathrm{dom}\, x$, then $\mathcal{A}$ is uniformly asymptotically stable for (1). If the Lyapunov function is a proper Lyapunov function for $(\mathcal{A}, O)$, then the basin of attraction for $\mathcal{A}$ contains O.*

The simplest way to rule out solutions that keep a Lyapunov function equal to a positive constant is by finding a *(proper) strict Lyapunov function for* $(\mathcal{A}, O)$, which is a (proper) Lyapunov function for $(\mathcal{A}, O)$ that also satisfies:

(L2$'$) For each $x \in (C \cap O) \setminus \mathcal{A}$ and $f \in F(x)$,
$\langle \nabla V(x), f \rangle < 0$.

(L3$'$) For each $x \in (D \cap O) \setminus \mathcal{A}$ and $g \in G(x)$,
$V(g) - V(x) < 0$.

Theorem 5 *Let $\mathcal{A} \subset O \subset \mathbb{R}^n$ with $\mathcal{A}$ compact and O open. Under Assumption 1, if there exists a strict Lyapunov function for $(\mathcal{A}, O)$, then $\mathcal{A}$ is uniformly asymptotically stable for (1). If there exists a proper strict Lyapunov function for $(\mathcal{A}, O)$, then $\mathcal{A}$ is uniformly asymptotically stable for (1) with basin of attraction containing O.*

While a strict Lyapunov function can be difficult to find, and this fact has motivated other more sophisticated stability analysis tools that have appeared in the literature, it is reassuring to know that whenever $\mathcal{A}$ is compact and asymptotically stable, there exists a proper strict Lyapunov function for $(\mathcal{A}, \mathcal{B}_\mathcal{A})$.

Theorem 6 *Under Assumption 1, if the compact set $\mathcal{A}$ is asymptotically stable for (1), then there exists a proper strict Lyapunov function for $(\mathcal{A}, \mathcal{B}_\mathcal{A})$. More specifically, for each $\lambda > 0$ there exists a smooth function V with $\mathrm{dom}\, V = \mathcal{B}_\mathcal{A}$ that $V(x) = 0$ if and only if $x \in \mathcal{A}$, $\lim_{i \to \infty} V(x_i) = \infty$ when the sequence $\{x_i\}_{i=0}^{\infty}$, satisfying $x_i \in \mathcal{B}_\mathcal{A}$ for all $i \in \mathbb{Z}_{\geq 0}$, is unbounded or tends to the boundary of $\mathcal{B}_\mathcal{A}$, and such that:*
1. *For all $x \in C \cap \mathcal{B}_\mathcal{A}$ and $f \in F(x)$, $\langle \nabla V(x), f \rangle \leq -\lambda V(x)$.*
2. *For all $x \in D \cap \mathcal{B}_\mathcal{A}$ and $g \in G(x)$, $V(g) \leq \exp(-\lambda) V(x)$.*

Summary and Future Directions

Under Assumption 1, stability theory for hybrid dynamical systems is very similar to stability theory for differential equations or difference equations with continuous right-hand sides. In particular, Lyapunov functions are a very common analysis tool for hybrid dynamical systems, though a Lyapunov function can be difficult to find in the same way that they are challenging to find for classical systems. With stability theory for hybrid dynamical systems firmly in place, future research is expected to exploit this theory more fully for the development of control algorithms with new capabilities.

Abstract

The notion of stability allows to study the qualitative behavior of dynamical systems. In particular it allows to study the behavior of trajectories close to an equilibrium point or to a motion.

The notion of stability that we discuss has been introduced in 1882 by the Russian mathematician A.M. Lyapunov, in his doctoral thesis; hence, it is often referred to as Lyapunov stability. In this entry we discuss and characterize Lyapunov stability for linear systems.

Keywords

Eigenvalues; Equilibrium points; Linear systems; Motions; Stability

Introduction

Consider a linear, time-invariant, finite-dimensional system, i.e., a system described by equations of the form

$$\begin{aligned}
\sigma x &= Ax + Bu, \\
y &= Cx + Du,
\end{aligned} \tag{1}$$

with $x(t) \in I\!R^n$, $u(t) \in I\!R^m$, $y(t) \in I\!R^p$ and $A \in I\!R^{n \times n}$, $B \in I\!R^{n \times m}$, $C \in I\!R^{p \times n}$, and $D \in I\!R^{p \times m}$ constant matrices. In Eq. (1) $\sigma x(t)$ stands for $\dot{x}(t)$ if the system is continuous-time and for $x(t + 1)$ if the system is discrete-time. Since the system is time-invariant, it is assumed, without loss of generality, that all signals are defined for $t \geq 0$, that is, if the system is continuous-time, then $t \in I\!R^+$, i.e., the set of non-negative real numbers, whereas if the system is discrete-time, then $t \in Z^+$, i.e., the set of non-negative integers. For ease of notation, the argument "t" is dropped whenever this does not cause confusion, and we use the notation $t \geq 0$ to denote either $I\!R^+$ or Z^+. Finally, we use either $x(t, x(0), u)$ or $x(t)$ to denote the solution of the first of equations (1) at a given time $t \geq 0$, with the initial condition $x(0)$ and the input signal u. The former is used when it is important to keep track of the initial state and external input u, whereas the latter is used whenever there is not such a need.

Definition 1 (Equilibrium) Consider the system (1). Assume the input u is constant, i.e., $u(t) = u_0$ for all $t \geq 0$ and for some constant

u_0. A state x_e is an equilibrium of the system associated to the input u_0 if $x_e = x(t, x_e, u_0)$, for all $t \geq 0$.

Proposition 1 (Equilibria of linear systems) *Consider the system ([1](#)) and assume $u(t) = u_0$, for all t, where u_0 is a constant vector. Then the following hold.*

- *If $u_0 = 0$ then the origin is an equilibrium.*
- *For continuous-time systems, if A is invertible, for any u_0 there is a unique equilibrium $x_e = -A^{-1}Bu_0$. If A is not invertible, the system has either infinitely many equilibria or it has no equilibria.*
- *For discrete-time systems, if $I - A$ is invertible, for any u_0 there is a unique equilibrium $x_e = (I - A)^{-1}Bu_0$. If $I - A$ is not invertible, the system has either infinitely many equilibria or it has no equilibria.*

Proposition 2 *Consider the continuous-time, time-invariant, linear system*

$$\dot{x} = Ax + Bu,$$
$$y = Cx + Du,$$

and the initial condition $x(0) = x_0$. Then, for all $t \geq 0$,

$$x(t) = e^{At}x_0 + \int_0^t e^{A(t-\tau)}Bu(\tau)d\tau \quad (2)$$

and

$$y(t) = Ce^{At}x_0 + \int_0^t Ce^{A(t-\tau)}Bu(\tau)d\tau + Du(t). \quad (3)$$

Proposition 3 *Consider the discrete-time, time-invariant, linear system (to simplify the notation we use $x^+(t)$ to denote $x(t + 1)$ and we drop the argument t)*

$$x^+ = Ax + Bu,$$
$$y = Cx + Du,$$

and the initial condition $x(0) = x_0$. Then, for all $t \geq 0$,

$$x(t) = A^t x_0 + \sum_{i=0}^{t-1} A^{t-1-i}Bu(i) \quad (4)$$

and

$$y(t) = CA^t x_0 + \sum_{i=0}^{t-1} CA^{t-1-i}Bu(i) + Du(t). \quad (5)$$

Definitions

In this section we provide some notions and definitions which are applicable to general dynamical systems.

Definition 2 (Lyapunov stability) Consider the system ([1](#)) with $u(t) = u_0$, for all $t \geq 0$ and for some constant u_0. Let x_e be an equilibrium point. The equilibrium is stable (in the sense of Lyapunov) if for every $\epsilon > 0$ there exists a $\delta = \delta(\epsilon) > 0$ such that $\|x(0) - x_e\| < \delta$ implies $\|x(t) - x_e\| < \epsilon$, for all $t \geq 0$, where the notation $\|\cdot\|$ denotes the Euclidean norm in $\mathbb{R}^n$.

In stability theory the quantity $x(0) - x_e$ is called initial perturbation, and $x(t)$ is called perturbed evolution. Therefore, the definition of stability can be interpreted as follows. An equilibrium point x_e is stable if however we select a *tolerable* deviation ϵ, there exists a (possibly small) neighborhood of the equilibrium x_e such that all initial conditions in this neighborhood yield trajectories which are within the *tolerable* deviation.

The property of stability dictates a condition on the evolution of the system for all $t \geq 0$. Note, however, that in the definition of stability, we have not requested that the perturbed evolution converge asymptotically, that is, for $t \to \infty$, to x_e. This convergence property is very important in applications, as it allows to characterize the situation in which not only the perturbed evolution remains close to the unperturbed evolution, but it also converges to the initial (unperturbed) evolution. To capture this property we introduce a new definition.

Definition 3 (Asymptotic stability) Consider the system (1) with $u(t) = u_0$, for all $t \geq 0$ and for some constant u_0. Let x_e be an equilibrium point. The equilibrium is asymptotically stable if it is stable and if there exists a constant $\delta_a > 0$ such that $\|x(0) - x_e\| < \delta_a$ implies $\lim_{t \to \infty} \|x(t) - x_e\| = 0$.

In summary, an equilibrium point is asymptotically stable if it is stable, and whenever the initial perturbation is inside a certain neighborhood of x_e, the perturbed evolution converges, asymptotically, to the equilibrium point, which is thus said to be attractive. From a physical point of view, this means that all sufficiently small initial perturbations give rise to effects which can be a priori bounded (stability) and which vanish asymptotically (attractivity).

It is important to highlight that, in general, attractivity does not imply stability: it is possible to have an equilibrium of a system which is not stable (i.e., it is unstable), yet for all initial perturbations, the perturbed evolution converges to the equilibrium. This however is not the case for linear systems, as discussed in section "Stability of Linear Systems". We conclude the section with two simple examples illustrating the notions that have been introduced.

Example 1 Consider the discrete-time system $x^+ = -x$, with $x(t) \in I\!R$. This system has a unique equilibrium at $x_e = 0$. Note that for any initial condition $x_0 \in I\!R$, one has

$$x_{2t-1} = -x_0, \qquad x_{2t} = x_0,$$

for all $t \geq 1$ and integer. This implies that the equilibrium is stable, but not attractive.

Example 2 Consider the continuous-time system

$$\dot{x}_1 = \omega x_2, \qquad \dot{x}_2 = -\omega x_1,$$

with ω a positive constant. The system has a unique equilibrium at $x_e = 0$. This equilibrium is stable, but not attractive. To see this note that, along the trajectories of the system, $x_1 \dot{x}_1 + x_2 \dot{x}_2 = 0$, and this implies that, along the trajectories of the system, $x_1^2(t) + x_2^2(t)$ is

constant, i.e., $x_1^2(t) + x_2^2(t) = x_1^2(0) + x_2^2(0)$. Therefore, the state of the system remains on the circle centered at the origin and with radius $\sqrt{x_1^2(0) + x_2^2(0)}$, for all $t \geq 0$: the condition for stability holds with $\delta(\epsilon) = \epsilon$.

Definition 4 (Global asymptotic stability) Consider the system (1) with $u(t) = u_0$, for all $t \geq 0$ and for some constant u_0. Let x_e be an equilibrium point. The equilibrium is globally asymptotically stable if it is stable and if, for all $x(0)$, $\lim_{t \to \infty} \|x(t) - x_e\| = 0$.

The property of (global) asymptotic stability can be strengthened imposing conditions on the convergence speed of $\|x(t) - x_e\|$.

Definition 5 (Exponential stability) Consider the system (1) with $u(t) = u_0$, for all $t \geq 0$ and for some constant u_0. Let x_e be an equilibrium point. The equilibrium is exponentially stable if there exists $\lambda > 0$, in the case of continuous-time systems, and $0 < \lambda < 1$ in the case of discrete-time systems, such that for all $\epsilon > 0$, there exists a $\delta = \delta(\epsilon) > 0$ such that $\|x(0) - x_e\| < \delta$ implies $\|x(t) - x_e\| < \epsilon e^{-\lambda t}$, in the case of continuous-time systems, and $\|x(t) - x_e\| < \epsilon \lambda^t$, in the case of discrete-time systems, for all $t \geq 0$.

Definition 6 (Stability of motion) Consider the system (1). Let

$$\mathcal{M} = \{(t, x(t)) \in T \times I\!R^n\},$$

with $x(t) = x(t, x_0, u)$, for given x_0 and u, and $T = I\!R^+$, in the case of continuous-time systems, and $T = Z^+$, in the case of discrete-time systems, be a motion. The motion is stable if for every $\epsilon > 0$ there exists a $\delta = \delta(\epsilon) > 0$ such that $\|x(0) - x_0\| < \delta$ implies

$$\|x(t, x(0), u) - x(t, x_0, u)\| < \epsilon, \qquad (6)$$

for all $t \geq 0$.

The notion of stability of a motion is substantially the same as the notion of stability of an equilibrium. The important issue is that the time-parametrization is important, i.e., a motion is stable if, for small initial perturbations, the

perturbed evolution is close, for any fixed $t \geq 0$, to the non-perturbed evolution. This does not mean that if the perturbed and unperturbed trajectories are close, then the motion is stable: in fact the trajectories may be close but may be followed with different timing, which means that for some $t \geq 0$ condition (6) may be violated.

Stability of Linear Systems

The notion of stability relies on the knowledge of the trajectories of the system. As a result, even if this notion is very elegant and useful in applications, it is in general hard to assess stability of an equilibrium or of a motion. There are, however, classes of systems for which it is possible to give stability conditions without relying upon the knowledge of the trajectories. Linear systems belong to one such class. In this section we study the stability properties of linear systems, and we show that, because of the linear structure, it is possible to assess the properties of stability and attractivity in a simple way. To begin with, we recall some properties of linear systems.

Proposition 4 *Consider a linear, time-invariant system. (Asymptotic) stability of one motion implies (asymptotic) stability of all motions. In particular, (asymptotic) stability of any motion implies and is implied by (asymptotic) stability of the equilibrium $x_e = 0$.*

The above statement, together with the result in Proposition 1, implies the following important properties.

Proposition 5 *If the origin of a linear system is asymptotically stable, then, necessarily, the origin is the only equilibrium of the system for $u = 0$. Moreover, asymptotic stability of the zero equilibrium is always global. Finally, asymptotic stability implies exponential stability.*

The above discussion shows that the stability properties of a motion (e.g., an equilibrium) of a linear system are inherited by all motions of the system. Moreover, for linear systems, local properties are always global properties. This means

that, with some abuse of terminology, we can refer the stability properties to the linear system, for example, we say that a linear system is stable to mean that all its motions are stable. Stability properties of a linear, time-invariant system are therefore properties of the *free* evolution of its state: for this class of systems, it is possible to obtain simple stability tests.

Proposition 6 *A linear, time-invariant system is stable if and only if $\|e^{At}\| \leq k$, for continuous-time systems, or $\|A^t\| \leq k$, for discrete-time systems, for all $t \geq 0$ and for some $k > 0$. It is asymptotically stable if and only if $\lim_{t \to \infty} e^{At} = 0$, for continuous-time systems, or $\lim_{t \to \infty} A^t = 0$, for discrete-time systems. To state the next result we need to define the geometric multiplicity of an eigenvalue. To this end we recall a few facts. Consider a matrix $A \in I\!R^{n \times n}$ and a polynomial $p(\lambda)$. The polynomial $p(\lambda)$ is a zeroing polynomial for A if $p(A) = 0$. Note that, by Cayley-Hamilton Theorem, the characteristic polynomial of A is a zeroing polynomial for A. Among all zeroing polynomials there is a unique monic polynomial $p_M(\lambda)$ with smallest degree. This polynomial is called the minimal polynomial of A. Note that the minimal polynomial of A is a divisor of the characteristic polynomial of A. If A has $r \leq n$ distinct eigenvalues $\lambda_1, \ldots, \lambda_r$, then*

$$p_M(\lambda) = (\lambda - \lambda_1)^{m_1}(\lambda - \lambda_2)^{m_2} \cdots (\lambda - \lambda_r)^{m_r},$$

where the number m_i denotes, by definition, the geometric multiplicity of λ_i, for $i = 1, \cdots, r$. This means that the geometric multiplicity of λ_i equals the multiplicity of λ_i as a root of $p_M(\lambda)$. Recall, finally, that the multiplicity of λ_i as a root of the characteristic polynomial is called algebraic multiplicity.

Proposition 7 *The equilibrium $x_e = 0$ of a linear, time-invariant system is stable if and only if the following conditions hold.*

- *In the case of continuous-time systems, the eigenvalues of A with geometric multiplicity equal to one have non-positive real part, and the eigenvalues of A with geometric multiplicity larger than one have negative real part.*

- *In the case of discrete-time systems, the eigenvalues of A with geometric multiplicity equal to one have modulo not larger than one, and the eigenvalues of A with geometric multiplicity larger than one have modulo smaller than one.*

Proof   Let $\lambda_1, \lambda_2, \cdots, \lambda_r$, with $r \geq 1$, be the distinct eigenvalues of A, i.e., the distinct roots of the characteristic polynomial of A. Then

$$e^{At} = \sum_{i=1}^{r} \sum_{k=1}^{m_i} R_{ik} \frac{t^{k-1}}{(k-1)!} e^{\lambda_i t},$$

for some matrices R_{ik}, where m_i is the geometric multiplicity of the eigenvalue λ_i. This matrix is bounded if and only if the conditions in the statement hold. Similarly,

$$A^t = \sum_{i=1}^{r} \sum_{k=1}^{m_i} R_{ik} \frac{t^{k-1}}{(k-1)!} \lambda_i^{t-k+1},$$

for some matrices R_{ik}, and this is bounded if and only if the conditions in the statement hold.   ◁

Proposition 8 *The equilibrium $x_e = 0$ of a linear, time-invariant system is asymptotically stable if and only if the following conditions hold.*
- *In the case of continuous-time systems, the eigenvalues of A have negative real part.*
- *In the case of discrete-time systems, the eigenvalues of A have modulo smaller than one.*

Proof   The proof is similar to the one of the previous proposition, once it is noted that, for the considered class of systems and as stated in Proposition 6, asymptotic stability implies and is implied by boundedness and convergence of e^{At} or A^t.   ◁

Remark 11.1 For linear, time-varying systems, i.e., systems described by equations of the form

$$\sigma x = A(t)x + B(t)u,$$
$$y = C(t)x + D(t)u,$$

it is possible to provide stability conditions in the spirit of the boundedness and convergence conditions in Proposition 6. These require the definition of a matrix, the so-called monodromy matrix, which describes the free evolution of the state of the system. It is, however, not possible to provide conditions in terms of eigenvalues of the matrix $A(t)$ similar to the conditions in Propositions 7 and 8.

We conclude this discussion with an alternative characterization of asymptotic stability in terms of linear matrix inequalities.

Proposition 9 *The equilibrium $x_e = 0$ of a linear, time-invariant system is asymptotically stable if and only if the following conditions hold.*
- *In the case of continuous-time systems, there exists a symmetric positive definite matrix $P = P'$ such that $A'P + PA < 0$.*
- *In the case of discrete-time systems, there exists a symmetric positive definite matrix $P = P'$ such that $A'PA - P < 0$.*

To complete our discussion we stress that stability properties are invariant with respect to changes in coordinates in the state space.

Corollary 1 *Consider a linear, time-invariant system and assume it is (asymptotically) stable. Then any representation obtained by means of a change of coordinates of the form $x(t) = L\hat{x}(t)$, with L constant and invertible, is (asymptotically) stable.*

Proof   The proof is based on the observation that the change of coordinates transforms the matrix A into $\tilde{A} = L^{-1}AL$ and that the matrices A and $\tilde{A}$ are similar, that is, they have the same characteristic and minimal polynomials.   ◁

Summary and Future Directions

The property of Lyapunov stability is instrumental to characterize the qualitative behavior of dynamical systems. For linear, time-invariant systems, this property can be studied on the basis of

the location, and multiplicity, of the eigenvalues of the matrix A. The property of Lyapunov stability can be studied for more general classes of systems, including nonlinear systems, distributed parameter systems, and hybrid systems, to which the basic definitions given in this article apply.

State Estimation for Batch Processes

Wolfgang Mauntz
Fakultät Bio- und Chemieingenieurwesen, Technische Universität Dortmund, Dortmund, Germany

Abstract

The information about certain safety or quality parameters during a batch process is valuable for a variety of reasons. In case a direct measurement is too expensive, too slow or nonexisting, a state estimator estimating the desired quantities based on a model and various other measurements may be a good alternative. The most prominent method is calorimetry, where the heat of reaction is measured. This entry gives an overview of different alternatives that support a safe and successful batch operation.

Keywords

Calorimetry; Observer; Soft sensor; State estimator

Introduction

Continuous processes are used to produce a product at a constant rate. They are designed to operate at constant conditions, i.e., the state of the process (conversion, temperatures, pressures, concentrations, etc.) does not vary. In contrast, (semi-)batch processes execute a recipe which means that they are typically operated within a wide range of states. The state of the (semi-batch) process should constantly be monitored. This information is useful for several purposes:

- *Process safety:* abnormal process states such as the accumulation of hazardous substances or reactive materials may lead to dangerous situations such as runaway reactions. The earlier an abnormal state is detected, the better it can be corrected, and the higher is the probability that loss can be avoided.

- *Quality:* if the batch is not operated along the standard trajectory, off-spec product may result which in turn results in extra effort and/or second-grade product if this is discovered in time and in a customer complaint if not discovered before delivery.
- *Profit:* the better the state is known, the less conservative the underlying control scheme needs to be and the more the process can be pushed to its limits. This may lead to a higher throughput, less by-products, or less energy consumption. Advanced control schemes which are typically applied for this purpose require knowledge of the state of the process.

The literature offers a wide range of ways to monitor a batch process. In some processes, the observation of simple measurements like temperatures, pressures, and the time that a process step takes for execution is sufficient to guarantee for safe standard product in minimum time. Examples include some melt-polymerizations.

However, as soon as the process is more complex, more information than just temperatures and pressures is required to monitor the process to meet the goals mentioned above. It may be sufficient to measure other easy to measure properties like conductivities, flow rates, pH values, sound velocities, attenuations, etc. However, in many cases these measurements do not give the complete state of the system. Properties like complex gas phase compositions cannot be measured this way. This might require the installation of more sophisticated measurements as, e.g., NIR spectroscopy, online gas chromatography, Raman spectroscopy, or ion mobility spectroscopy. These measurements require significant effort in terms of installation cost and maintenance. In other situations, no online measurement may be available at all. These cases include the measurement of the distribution of the molecular weight in a polymer melt.

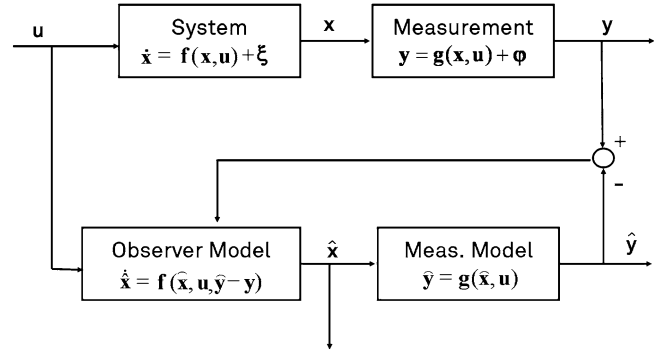
In these cases, where direct online measurements are either too expensive or not available at all, several methods are available to obtain information on the status of the batch (▶ Estimation, Survey on).

- *Statistical Methods*
  Experiences from historical batches are used in a statistical way to predict whether a batch runs normally. This can, e.g., be accomplished by defining a golden batch and a corresponding corridor around these trajectories. More sophisticated methods use principal component analysis (PCA) or partial least squares (PLS) to get a hint at abnormal situations. These methods are even capable of pointing at the origin of a possible problem. They are restricted to problem detection and typically cannot be used for control purposes.
- *Model-Based State Estimation*
  The state of the system (temperatures, pressures, concentrations, etc.) is estimated online which allows for problem detection as well as control applications. This method will be described in more detail in the next chapter.

General reviews of state estimation techniques can be found in Besancon (2007), Schei (2008), and a review of industrial applications is, e.g., given in Fortuna et al. (2007).

Model-Based State Estimation

The basic idea of a state estimator (which is frequently also called *observer* or *soft sensor*) is to run a mathematical model of the process in parallel to the process itself, to compare the available measurements to the values which are predicted by the model, and to correct the estimated state by a suitable function of the observed error, usually an additive correction term that depends on the error. For a state estimator to converge to the true state, the considered system needs to be observable. For details, see ▶ Controllability and Observability. The scheme of a state estimator is sketched in Fig. 1. The real system processes the input $\mathbf{u}$ to give the system state $\mathbf{x}$ which is affected by the system noise $\boldsymbol{\xi}$. The measurements $\mathbf{y}$ are perturbed by the measurement noise $\boldsymbol{\varphi}$. The model predicts a system state $\hat{\mathbf{x}}$ and a measurement $\hat{\mathbf{y}}$. The difference between the measured value $\mathbf{y}$ and predicted value $\hat{\mathbf{y}}$ is then fed back to correct the estimated state.

State Estimation for Batch Processes, Fig. 1 Principle of a state estimator


For **linear systems**, the most commonly used state estimators are the *Luenberger observer* and the *Kalman filter* (▶ Kalman Filters). Both multiply the prediction error $(\mathbf{y} - \hat{\mathbf{y}})$ by a weighting matrix $\mathbf{K}$ to update the estimated state $\hat{\mathbf{x}}$:

$$\dot{\hat{\mathbf{x}}} = \mathbf{A}\hat{\mathbf{x}} + \mathbf{B}\mathbf{u} + \mathbf{K}(\mathbf{y} - \hat{\mathbf{y}})$$

The two techniques use different approaches for determining the matrix $\mathbf{K}$:

Luenberger Observer The basic assumption is that the deviation $\mathbf{e}(t)$ between $\mathbf{x}$ and $\hat{\mathbf{x}}$ is due to wrong initial values $\hat{\mathbf{x}}_0$. $\mathbf{K}$ is computed by choosing the desired speed of convergence of the error

$$\dot{\mathbf{e}}(t) = \dot{\mathbf{x}}(t) - \dot{\hat{\mathbf{x}}}(t)$$
$$= (\mathbf{A} - \mathbf{K}\mathbf{C})\,\mathbf{e}(t)$$

to zero. This is done by placing the eigenvalues of the matrix $(\mathbf{A} - \mathbf{K}\mathbf{C})$ in the left half plane.

Kalman Filter The basic assumption is that the error $\mathbf{e}(t)$ is caused by white noise in the system ξ as well as in the measurement φ. The idea is to minimize the expectation of the quadratic error

$$\min_{\hat{\mathbf{x}}} \quad E\left((\hat{\mathbf{x}}(t) - \mathbf{x}(t))^T (\hat{\mathbf{x}}(t) - \mathbf{x}(t))\right).$$

$\mathbf{K}$ is computed from the noise covariance matrices and the system dynamics and varies with time.

The tuning of the state estimators is not trivial. The larger the absolute value of the eigenvalues in the Luenberger approach, the faster the error will converge to zero but the more prone the state estimator will be to measurement noise. A similar trade-off exists for the Kalman filter where the covariance matrices of the noise terms ξ and φ and the covariance of the initial state ξ_0 need to be defined.

For **nonlinear systems**, a variety of approaches is available. The most frequently used estimators are based on using the nonlinear model for the prediction of the state and linearizations of the system dynamics are used to update the matrix $\mathbf{K}$. The *extended Kalman filter (EKF)* (▶ Extended Kalman Filters) and the *extended Luenberger observer (ELO)* are representatives of this class of approaches. The EKF is most widely used. Extensions are the *constrained EKF* and the *unscented EKF*.

As examples are known where the EKF fails due the nonlinearity of the system, methods based on ideas other than the linearization of system dynamics have been developed. These methods include the *moving horizon estimator* (MHE) (▶ Moving Horizon Estimation) and the *particle filter*. Because of the increasing capabilities of modern computers and significant improvements in dynamic optimization algorithms, the MHE is a very promising alternative. The idea of the method is to minimize the sum of the squared errors of the system noise ξ_l, the measurement noise φ_l, and the error of the initial state ξ_{k-N} which are weighted by weighing matrices $\mathbf{P}_k$, $\mathbf{Q}$ and $\mathbf{R}$ over a predefined horizon of past sampling steps $k - N, \ldots, k$

$$\min_{\xi_i,\varphi_j} \quad \xi_{k-N}^T \mathbf{P}_k^{-1}\xi_{k-N} \; + \; \sum_{l=k-N+1}^{k-1} \xi_l^T \mathbf{Q}^{-1}\xi_l$$
$$+ \sum_{l=k-N+1}^{k} \varphi_l^T \mathbf{R}^{-1}\varphi_l$$

$s.t.$ the system model and the measurement equations are satisfied and further inequality constraints (e.g., physical limits of variables) hold.

The possibility to define constraints on the estimated states, e.g., that concentrations must be nonnegative, is an important advantage of the MHE approach. If the horizon is reduced to one single measurement, the constrained extended Kalman filter results which combines the simplicity of the EKF with the possibility to include constraints on the estimated states. Efficient implementations of the MHE have led to the method being capable of estimating the state of rather large systems in real time (Diehl et al. 2006; Küpper and Engell 2007).

Calorimetry

Temperature measurements are probably the cheapest available measurements in chemical processes, and most plants are typically well equipped with temperature sensors. To exploit temperature measurements, e.g., for the observation of exothermic or endothermic reactions, heat balances are set up and solved for the heat of reaction which then enables the computation of the reaction rate. This is typically referred to as **calorimetry**. Reviews are given, e.g., in Hergeth (2006), McKenna et al. (2000), and Landau (1996). For a jacketed reactor, the heat balance around a semi-batch reactor typically reads (see also Fig. 2)

$$C_{P,R}\frac{dT_R}{dt} = \dot{Q}_R + kA(T_J - T_R)$$
$$+ \sum_i \dot{m}_{F,i} c_{p,Fi}(T_{F,i} - T_R), \quad (1)$$

where $\dot{Q}_R$ represents the heat of reaction, kA the overall heat transfer coefficient between the reactor content and the jacket, T_R the reactor temperature, T_J the jacket temperature, T_F the feed temperature, $C_{P,R}$ the overall heat capacity of the reactor, and the last term on the right side is the enthalpy added by the feed to the reactor. If kA is known, $\dot{Q}_R$ can directly be computed as all other quantities in Eq. (1) are known or measured. This is referred to as *heat flow calorimetry*.

In industrial practice, kA usually is not known and varies over time due to changes of the filling level, changes of the viscosity of the reaction mixture, and fouling. Then other heat balances and measurements can be added to enable a direct computation or estimation of kA. Typically, the jacket heat balance is chosen

$$C_{P,J}\frac{dT_J}{dt} = kA(T_R - T_J) + kA_{\text{jack}}(T_{\text{env}} - T_J)$$
$$+ \dot{m}_J\, c_{p,J}\,(T_{J,in} - T_J). \quad (2)$$

If necessary, also other phenomena like direct heat losses from the reactor content to the environment or the influence of the reactor lid can be taken into account by adding additional terms or additional heat balances. This method is called *heat balance calorimetry*.

In order to compute $\dot{Q}_R$ and kA from Eqs. (1) and (2), two different approaches can be used:
1. Equations (1) and (2) are solved to give

$$(3a)$$
$$\widehat{kA} = \frac{C_{P,J}\frac{dT_J}{dt} - kA_{\text{jack}}(T_{\text{env}} - T_J) - \dot{m}_J\, c_{p,J}\,(T_{J,in} - T_J)}{T_R - T_J}$$

$$\hat{\dot{Q}}_R = C_{P,R}\frac{dT_R}{dt} - kA(T_J - T_R) - \sum_i \dot{m}_{F,i} c_{p,Fi}(T_{F,i} - T_R). \quad (3b)$$

**State Estimation for
Batch Processes, Fig. 2**
The reactor and its jacket
as considered for
calorimetry

In this approach, the derivatives need to be computed from the measurements which introduces noise in the evaluation and requires a filtering either of the derivatives or of the estimates.

2. Equations (1) and (2) are implemented in a nonlinear state estimator. To estimate the unknown quantities $\widehat{kA}$ and $\hat{\dot{Q}}_R$ by this approach, additional assumptions about their dynamics must be made. A common approach is to add the so-called dummy derivatives

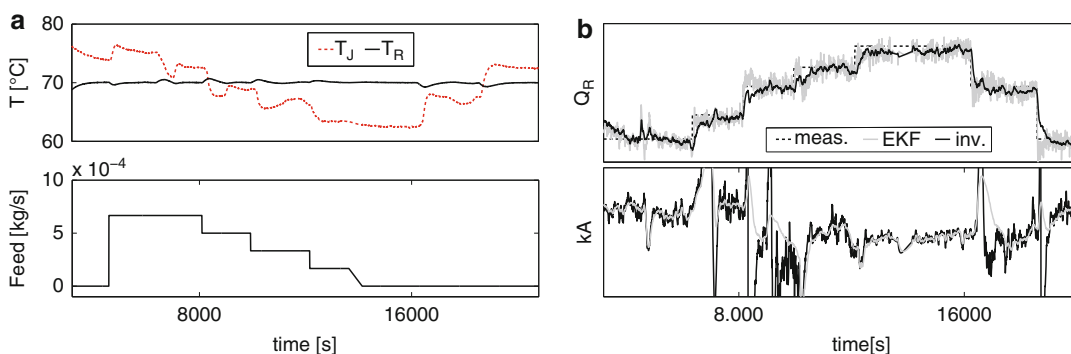
$$\frac{d\,\hat{\dot{Q}}_R}{dt} = 0$$
$$\frac{d\,\widehat{kA}}{dt} = 0,$$

The tuning of calorimetric estimation schemes has been discussed in the literature, but for each case, tests in simulation runs using recorded batch data should be performed.

Experimental results of the application of the direct solution equations (3) and an EKF for the estimation of $\dot{Q}_R$ and kA are shown in Fig. 3. A laboratory-scale 10 l metal reactor was filled with water. Cold water was injected into the reactor to simulate the feed of reactants. The reactor is

equipped with a heating rod by which different values of $\dot{Q}_R$ could be simulated. Figure 3a shows the measured temperatures and the feed stream; Fig. 3b shows the estimates. The dotted line displays the measured power uptake, the thin, black line represents the estimates from the evaluation of Eqs. (3), and the gray line shows the results obtained with an EKF. The EKF was tuned slightly more aggressively than the PT1-filter that was used to filter the values of $\hat{\dot{Q}}_R$ and $\widehat{kA}$ that were obtained from Eqs. (3).

It can be seen that the quality of both evaluation methods is comparable. A difference in performance can be seen in the estimation of kA at the points in time where $T_R \approx T_J$. This is due to the denominator in Eq. (3b) which becomes ≈ 0. At this point, kA is unobservable. The EKF estimates of kA are more smooth. This does not have an impact on the estimation of $\dot{Q}_R$ because the heat transfer from the jacket to the reactor is zero at this point. This behavior is of importance if $\widehat{kA}$ is used in other algorithms, e.g., for control purposes.

A practical problem is the determination of the parameters of the system model. Especially the heat capacity of the reactor $C_{P,R}$ is difficult to determine as it is not clear how much impact the reactor material has. Also the heat capacities of


State Estimation for Batch Processes, Fig. 3 Illustration of the results of direct estimation (Eqs. 3) and the use of an EKF. (**a**) Measured data. (**b**) Estimates from inverted equations (3) and EKF as well as measured $\hat{Q}_R$

intermediate products and mixtures with the raw materials and final products may not be known. That is why typically $C_{P,R}$ is considered a "free" parameter which is used to fit the estimates to measured data. If the adjustment of the available parameters is not sufficient to yield a satisfactory performance of the estimator, further extensions can be considered:

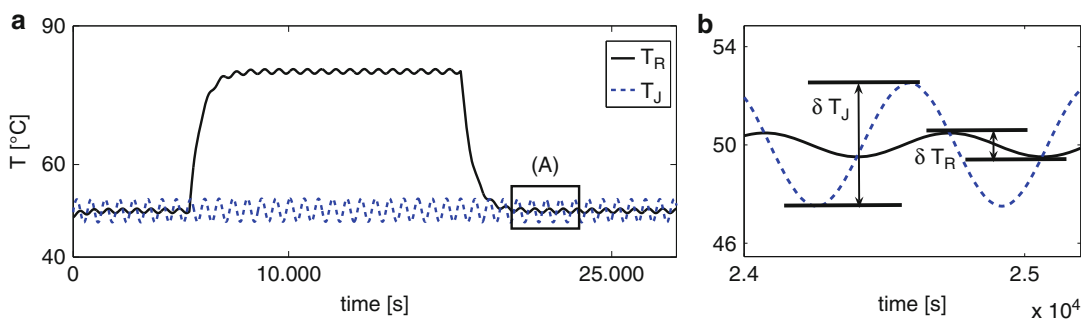
- If pressurized vessels are considered, the wall thickness may be considerable, and the heat accumulation may influence the results. In this case, the extension of the set of equations by an equation for the heat transfer through the wall may be considered (Saenz de Buruaga et al. 1997).

- If large-scale vessels are considered, the cooling fluid in the jacket may not be perfectly mixed, and a temperature gradient will be present. In many cases, cooling coils are welded on the outside surface of the reactor. In this case, the equation for the perfectly mixed jacket (Eq. (2)) should be replaced by a model for a plug flow reactor (Krämer and Gesthuisen 2005).

- For large industrial reactors, the perfect mixing assumption of the reactor contents does not necessarily hold true. Especially if polymerization reactions are considered, the reactor content may become rather viscous. A straightforward method to cope with this problem is a detailed computational fluid dynamics (CFD) simulation. However, due

to the numerical complexity, this appears infeasible for online applications. A practical alternative is the placement of several temperature sensors and using a weighted average over their readings. A different approach is the usage of a multi-zonal model, the idea of which resembles the idea of a CFD model; however the number of zones (elements) is much smaller (Bezzo et al. 2004).

Heat balance calorimetry becomes inaccurate if the mass flow through the jacket is so large that the temperature difference between the cooling stream entering the jacket and leaving the jacket $(T_{J,in} - T_J)$ is in the order of magnitude of the measurement error. This mode of operation is typically used in laboratory-scale reactors to avoid temperature gradients in the jacket. To estimate the states in such setups, a technique called *temperature oscillation calorimetry* (TOC) can be used. The idea is to add a small but well-measurable sinusoidal signal to the typically constant set point of the reactor temperature T_R (see Fig. 4 for an example). The reaction of the jacket temperature to the oscillating reactor temperature can be used to compute kA, e.g., by estimating its amplitude δT_J (Tietze et al. 1996) or by adding an additional equation which describes the second derivative of the reactor temperature $\frac{d^2 T_R}{dt^2}$ to the set of heat balances (Mauntz et al. 2007).

Calorimetry estimates the total heat of the reactions in the reactor. It can be used to estimate


State Estimation for Batch Processes, Fig. 4 Example experiment where TOC is applied. (**a**) Complete example. (**b**) Zoom of rectangle (A)

the overall chemical conversion of a process. Due to its integral character, the heat of reaction of parallel and consecutive reactions cannot be estimated separately (Hergeth 2006). However, if models of the chemical kinetics are known and reliable, it is possible to couple this kinetic model with calorimetry and to observe the complete state of the reaction based on calorimetric estimates. This solution may however not be robust as slight errors in the kinetic model may lead to significant errors in the estimates of all concentrations. In order to build a more robust state estimator, additional measurements should be installed and integrated into the state estimator. For example, for reactions including a phase change from the gas phase to the liquid phase, a pressure measurement may be suitable. For some polymerization reactions, sound velocity and sound attenuation measurements can be valuable (Brandt et al. 2012). The additional measurement can be incorporated into the observation scheme by augmenting the measurement model **g** (see Fig. 1) by the corresponding measurement equation.

Summary

In this contribution, different methods that can be used to determine the states of (semi-)batch reactions have been described. State estimation is useful to reconcile measurement errors and whenever direct online measurements are either too expensive or not available at all.

Linear state estimation is a mature topic. However as chemical batch reactors in most cases have nonlinear dynamics, nonlinear methods should be applied. Extensions of linear state estimators based on linearizations of the system (e.g., the EKF) are the most widely used nonlinear state estimators. However examples are known where these estimators fail. Thus, other approaches, e.g., based on online optimization (MHE), have been developed. They deliver promising results in terms of observation quality and computational speed even for large-scale systems.

The most widespread application of state estimation techniques in batch processes is calorimetry which is suitable for significantly exothermic or endothermic reactions. The heat balances around the reactor contents and the jacket are set up and solved. The estimated heat of reaction is used to estimate the chemical conversion of the process. The method makes use of commonly installed temperature measurements in the reactor. Extensions to include other measurements have been discussed. Problems that typically occur in laboratory-scale reactors can be overcome with the help of temperature oscillation calorimetry.

Abstract

Statistical process control has been successfully utilized for process monitoring and variation reduction in manufacturing applications. This entry aims to review some of the important monitoring methods. Topics discussed include: Shewhart's model, $\bar{X}$ and R control charts, EWMA and CUSUM charts for monitoring small process shifts, process monitoring for autocorrelated data, and integration of statistical and engineering (or automatic) control techniques. The goal is to provide readers from control theory, mechanical engineering, and electrical engineering an expository overview of the key topics in statistical process control.

Keywords

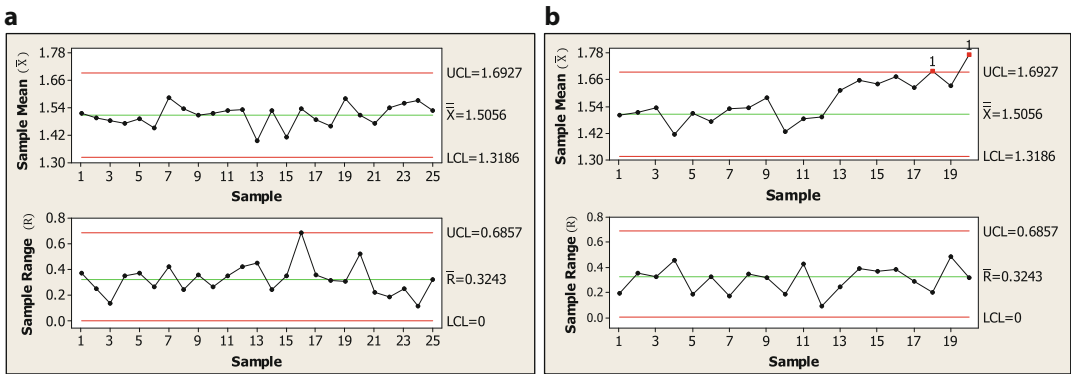
CUSUM; EWMA; Feedback control; Shewhart control chart; Time-series analysis

Introduction

Variation control is an important goal in manufacturing. The main set of tools for variation control used in discrete-part manufacturing industries up to the 1960s was developed by W. Shewhart in the 1920s and is known today as statistical process control, or SPC (Shewhart 1939). Shewhart's SPC model assumes that the process varies about a fixed mean and that consecutive observations from a process are independent, as follows:

$$Y_t = \mu_0 + \epsilon_t \qquad (1)$$

in which μ_0 is the in-control process mean and ϵ_t is iid (independent identically distributed) white noise $\epsilon \overset{\text{iid}}{\sim} N(0, \sigma^2)$. The Shewhart model can be used in distinguishing assignable cause variation from common cause variation. For example, a mean change from μ_0 to $\mu_1 = \mu_0 + \delta$ (where δ is the unknown magnitude of change) or a variance increase from σ_0^2 to σ_1^2 at an unknown point in time can be detected as assignable causes.

The objective of this entry is to highlight some of the important references in the SPC literature and to discuss similarities and joint applications SPC has with automatic process control. The literature on statistical process control and applications to engineering problems is vast; therefore, no effort is made for an exhaustive review. More complete reviews of the literature on statistical process control and adjustment methods can be found in texts including Montgomery (2013), Ryan (2011), and Del Castillo (2002).


Shewhart Control Charts

Shewhart's $\bar{X}$ and R control charts are used to distinguish between common cause and assignable causes of variation (Shewhart 1939) by monitoring, respectively, the process mean and process variance. "Common cause" variation is the natural variability of the process due to uncontrollable factors in the environment that is not avoidable without substantial changes

to the process. "Assignable cause" variation is due to unwanted disturbances or upsets to the process that can be detected and removed to produce acceptable quality products. When only common cause variation exists, the process is said to be operating "in statistical control." Assignable causes of variation include operator changes, machine calibration errors or raw material variation between suppliers.

Another concept that is closely related to the Shewhart's model is process capability. Process capability indices are used to assess whether the process is operating in a satisfactory manner with respect to the engineering specifications. It is crucial to attain a stable process (eliminating all problematic causes) before undertaking such a capability analysis because only when the samples come from a stable probability distribution can the future behavior of the process be predicted "within probability limits determined by the common cause system" (Box and Kramer 1992).

Figure 1 illustrates the two main phases, referred to as Phase I and Phase II, in constructing Shewhart charts (Sullivan 2002), using semiconductor lithography process data given in Montgomery (2013). It is desired to establish a statistical control of the width of the resist using $\bar{X}$ and R charts. Twenty-five preliminary subgroups, each of size five wafers, were taken at one-hour intervals and the resist width is measured. In Phase I, "retrospective analysis," the historical data from the process is analyzed to bring an initially out-of-control process into

Statistical Process Control in Manufacturing, Fig. 1 Shewhart $\bar{X}$ and R charts from (**a**) Phase I analysis and (**b**) Phase II analysis

statistical control. Subgroups $y_1, \ldots, y_n$ of size n are taken, and subgroup average $\bar{y}$ is used to monitor process mean μ_0, and the subgroup range is used to monitor standard deviation of the process mean $\sigma_{\bar{Y}} = \sigma/\sqrt{n}$. The upper and lower control limits are found for the $\bar{X}$ chart as $\{UCL, LCL\} = \mu_0 \pm L\sigma_{\bar{Y}}$ where L is a constant representing the width of the control limits. Commonly chosen three-sigma limits (i.e., $L = 3$) provide a probability $p = 0.0027$ that a single point falls outside the limits when process is in control ("false alarm probability"). Points that fall outside the control limits are investigated, and if an assignable cause was identified, then this point is omitted and control limits are recalculated. This is repeated until no further points plot outside the limits. In Phase II these charts are used to detect shifts in the process mean and variability.

The $\bar{X}$ and R charts from Phase I data in Fig. 1a indicate statistical control; hence the computed control limits can be used for Phase II monitoring. Twenty additional subgroups (also of size 5) are taken in Phase II while the control charts are in use. The Phase II charts shown in Fig. 1b indicate that process variability is stable but the process mean has shifted at subgroup 18. The general trend in the $\bar{X}$ chart indicates that process mean probably has shifted earlier around subgroup 13.

EWMA, CUSUM, and Changepoint Estimation

Shewhart charts can detect large magnitude process upsets reasonably well; however, they are relatively slow to detect small shifts. In order to reduce the reaction time for smaller shifts, a set of "runs" rules (e.g., two out of three runs beyond 2σ limits or four out of five runs beyond 1σ limits) has been proposed Western Electric (1956). A more systematic method is to accumulate information over successive observations using CUSUM and EWMA statistics rather than basing the detection on a single sample. In the cumulative sum (CUSUM) chart, a running total $\sum_{i=1}^{t}(\bar{Y}_t - \mu_0)$ is plotted against subgroup number t, and a shift from the in-control mean μ_0 is

signaled by an upward or downward linear trend in the plot. A two-sided CUSUM is defined as Woodall and Adams (1993):

$$S_t^{\pm} = \max\{\pm Z_t - k + S_{t-1}^{\pm}, 0\} \text{ for } t = 1, 2, \ldots \tag{2}$$

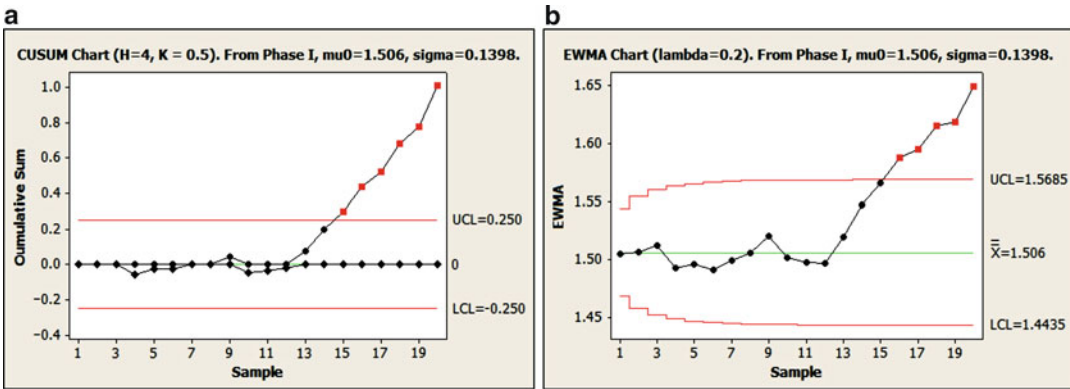
where S_t^{+} and S_t^{-} are the one-sided upper and lower cusums, respectively, $Z_t = (\bar{Y}_t - \mu_0)/\sigma_{\bar{Y}}$ is the standardized subgroup average, $k = |\mu_1 - \mu_0|/(2\sigma)$ is the reference value, and μ_1 is the level of process mean to be detected. An out-of-control signal is given at the first t for which $S_t > h$ where h is a suitably chosen threshold, usually selected based on the desired average number of samples to signal an alarm, also called the average run length (ARL). The recommended value for the threshold h is 4 or 5 (corresponding to four or five times the process standard deviation σ), and the value for the reference k is almost always taken as 0.5 (corresponding to shift size $|\mu_1 - \mu_0| = \sigma$) (Montgomery 2013).

Another chart that accumulates deviations over several samples is the exponentially weighted moving average (EWMA) which is based on the statistic (Lucas and Saccucci 1990)

$$Z_t = \lambda \bar{Y}_t + (1 - \lambda)Z_{t-1} \tag{3}$$

where $0 < \lambda < 1$ is a smoothing constant. Smaller λ provides large smoothing (similar to a large subgroup size n in the Shewhart charts). The starting value is the in-control mean $Z_0 = \mu_0$. It can be shown that Z_t is a weighted average of all previous sample means, where the weights decrease geometrically with the age of the subgroup mean. The EWMA statistic is plotted against the control limits $\mu_0 \pm L\sigma_{\bar{Y}}\sqrt{(\lambda/(2-\lambda))[1-(1-\lambda)^{2t}]}$. Shewhart charts that are effective for large shifts are more useful for Phase I, and CUSUM or EWMA charts that are effective for small shifts are more appropriate for Phase II.

We illustrate in Fig. 2 how to monitor with CUSUM and EWMA charts with the lithography data. The in-control process mean and standard deviation μ_0 and σ are found from the Phase I data. CUSUM upper and lower statistics $S_t^{\pm}$ computed with Phase II data are plotted in Fig. 2a

S


Statistical Process Control in Manufacturing, Fig. 2 Phase II charts for lithography data (**a**) CUSUM chart and (**b**) EWMA chart

(reference value $k = 0.5$ and threshold $h = 4$ are used.). The upper cusum statistic S_t^+ crosses the upper control limit indicating an upward shift at subgroup 15. The EWMA statistic applied with $\lambda = 0.2$ on Phase II data, shown Fig. 2b, crosses the upper control limit at subgroup 16. Both charts have improved the reaction times of the Shewhart chart.

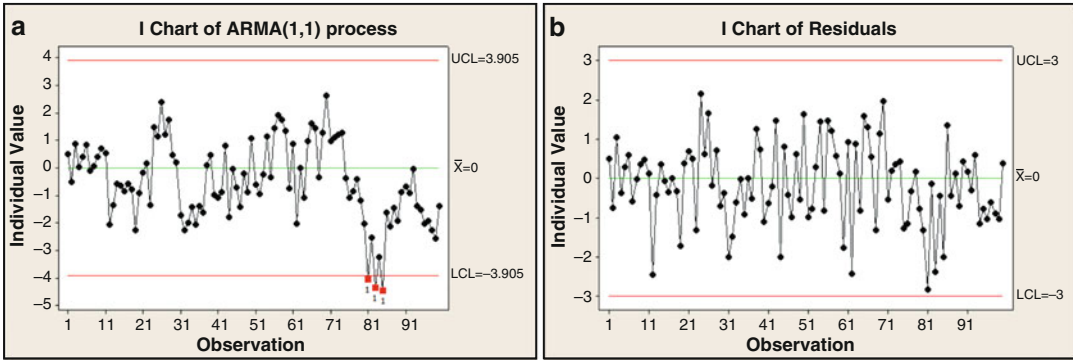
When a control chart signals an assignable cause, it does not indicate when the process change actually occurred. Estimating the instant of the change, or *changepoint* estimation, is especially useful in Phase I analysis where little is known about the process, and it is important to identify and remove the out-of-control samples from consideration (Hawkins et al. 2003; Basseville and Nikiforov 1993; Pignatiello and Samuel 2001). The process is modeled as

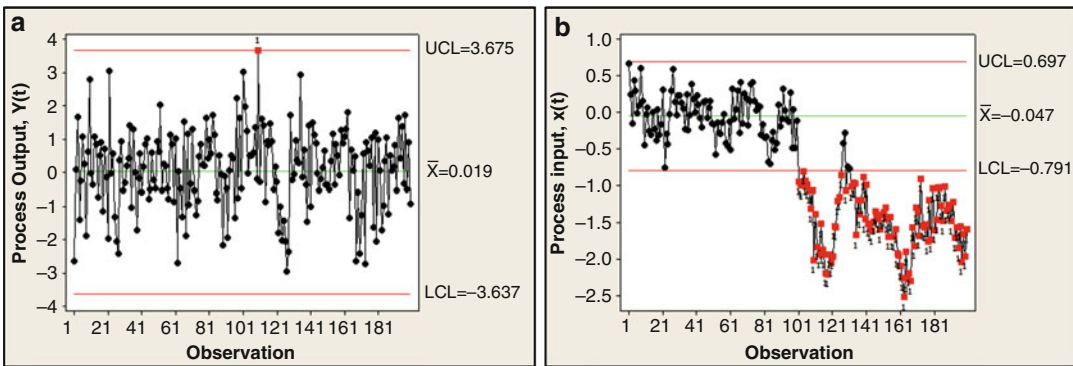
$$Y_i \sim N(\mu_1, \sigma^2) \text{ for } i = 1, 2, \dots, \tau$$
$$Y_i \sim N(\mu_2, \sigma^2) \text{ for } i = \tau + 1, \dots, n \quad (4)$$

where τ is the unknown changepoint, at which the in-control mean μ_1 is assumed to shift to a new value μ_2 assuming μ_1, σ are known but μ_2 is unknown. A generalized likelihood ratio (GLR) test statistic $\Lambda_t = \sum_{i=1}^{t} \log f_2(y_i)/f_1(y_i)$ is used to test the hypothesis of a changepoint against the null hypothesis that there is no change. Assuming normality $f(y) = 1/\sqrt{2\pi\sigma} \exp[-(y - \mu)^2/(2\sigma^2)]$ is the probability density function of the quality characteristic. The changepoint model

is equivalent to the CUSUM chart when all parameters μ_1, μ_2 and σ are known a priori. For the lithography Phase II data in Fig. 1b, it can be shown that the changepoint can be estimated as subgroup 13.

SPC on Controlled and Autocorrelated Processes

It is well known that automatic control performance relies heavily on the accuracy of the process models. An active field of research in recent years is the monitoring of controlled systems using SPC charts (Box and Kramer 1992) in order to reduce the effect of model accuracy. Shewhart charts can be used to monitor the output of a feedback-controlled process; however, as the controller effectively corrects the shift, only a short window of opportunity is provided to detect the shift (Vander Wiel et al. 1992). Tsung and Tsui (2008) showed that monitoring the control actions gives better run-length performance than monitoring the output for small- and medium-size shifts, and monitoring the output gives better performance for large shifts. In monitoring controlled processes, measurements taken at short intervals with positive autocorrelation usually inflate the rate of false alarms (Harris and Ross 1991). Widening the control limits and monitoring the residuals of a time-series model fitted to the observations are some of the strategies


Statistical Process Control in Manufacturing, Fig. 3 (**a**) Shewhart chart for autocorrelated process. (**b**) Shewhart chart for residuals


Statistical Process Control in Manufacturing, Fig. 4 (**a**) Shewhart chart for controlled process Y_t. (**b**) Shewhart chart for input X_t

employed to reduce the number of false alarms (Alwan and Roberts 1988).

To illustrate the effects of autocorrelation, we consider simulated data from an autoregressive moving average ARMA(1,1) time-series disturbance process $D_t = 0.8D_{t-1} + \epsilon_t - 0.3\epsilon_{t-1}$ (Box et al. 1994) defined with the white noise process $\epsilon_t \overset{iid}{\sim} N(0, 1^2)$ (with in-control mean $\mu_0 = 0$ and variance $\sigma_D^2 = 1.694$). Figure 3a shows a realization of the process monitored with a Shewhart chart (control limits at $\mu_0 \pm 3\sigma_D$). Due to autocorrelation, false alarms are signaled at samples 81–83. Figure 3b shows the control chart monitoring of the residuals of an ARMA(1,1) model. Residuals (standard normal with mean 0 and variance 1) are not autocorrelated, so the Shewhart chart for residuals does not signal any false alarms.

We illustrate monitoring of controlled processes with simulated data from a transfer function model $Y_t = 2X_{t-1} + D_t$ where X_t are the adjustments made on the process. A proportional integral control rule $X_t = -0.1Y_t - 0.15\sum_{i=1}^{t} Y_i$ is employed, and the disturbance D_t is assumed to follow the ARMA model considered earlier. As an assignable cause, the disturbance mean has shifted at sample 100 by a magnitude of $3\sigma_D$. Figure 4 shows the Shewhart charts monitoring the output Y_t and the input X_t. The effect of assignable cause (at sample 100) on the output is quickly removed by the controller; however, a sustained shift remains in the control input. The control chart for the input Fig. 4b signals the first alarm at sample 101 (much quicker) than the control chart for the output Fig. 4a which signals at sample 110.

Summary and Future Directions

In this entry we reviewed some of the commonly used statistical process monitoring methods for manufacturing systems. Due to space limitations, only several important topics including Phase I and Phase II monitoring with Shewhart, EWMA, and CUSUM charts were discussed, highlighting main applications with numerical examples. Other current research areas include multivariate methods for monitoring processes with multiple quality characteristics taking advantage of relationships among them (Lowry and Montgomery 1992), profile monitoring for processes that generate functional data (Woodall et al. 2004), multistage monitoring for processes with multiple processing steps and variation transmission (Tsung et al. 2008), and run-to-run EWMA control for semiconductor manufacturing processes that require handling of multiple types of products, operators, and machine tools (Butler and Stefani 1994).

Stochastic Adaptive Control

Tyrone Duncan and Bozenna Pasik-Duncan
Department of Mathematics, University of Kansas, Lawrence, KS, USA

Abstract

Stochastic adaptive control denotes the control of partially known stochastic control systems. The stochastic control systems can be described by discrete- or continuous-time Markov chains

or Markov processes, linear and nonlinear difference equations, and linear and nonlinear stochastic differential equations. The solution of a stochastic adaptive control problem typically requires the identification of the partially known stochastic system and the simultaneous control of the partially known system using the information from the concurrent identification scheme. Two desirable goals for the solution of a stochastic adaptive control problem are called self-tuning and self-optimality. Self-tuning denotes the convergence of the family of adaptive controls indexed by time to the optimal control for the true system. Self-optimizing denotes the convergence of the long-run average costs to the optimal long-run average cost for the true system. Typically to achieve the self-optimality, it is important that the family of parameter estimators from the identification scheme be strongly consistent, that is, this family converges (almost surely) to the true parameter values. Thus, with self-optimality, asymptotically a partially known system can be controlled as well as the corresponding known system.

Keywords

Bayesian estimation; Brownian motion; Markov processes; Self-tuning regulators

Motivation and Background

In almost every formulation of a stochastic control problem from a physical system, the physical system is incompletely known so the stochastic system model is only partially known. This lack of knowledge can often be described by some unknown parameters for a mathematical model, and the noise inputs for the model can describe unmodeled dynamics or perturbations to the system. The lack of knowledge of some parameters of the model can be modeled either by random variables with known prior distributions or as fixed unknown values. The former description requires Bayesian estimation, and the latter description requires parameter estimation such as least squares or maximum likelihood.

Stochastic adaptive control arose as a natural evolution from the results in stochastic control, and in particular it developed for some well-known control problems. The optimal control of Markov chains had been developed for some time, so it was natural to investigate the adaptive control of Markov chains. Mandl (1973) was probably the first to consider this adaptive control problem in generality. His conditions for strong consistency of a family of estimators were fairly restrictive. Borkar and Varaiya (1982) simplified the conditions for the estimation part of the problem by only requiring convergence of the estimators of the parameters so that the resulting transition probabilities of the Markov chain are identical to the transition probabilities for the true optimal solution.

A second major direction for stochastic adaptive control is described by ARMAX (autoregressive-moving average with exogenous inputs) models. These are discrete-time models that can be described in terms of polynomials in a time shift operator. A closely related and often equivalent model is multidimensional linear difference equations in a state-space form. Since the solution of the infinite time horizon stochastic control problem was available in the late 1950s, it was natural to consider the adaptive control problem. Methods such as least squares, weighted least squares, maximum likelihood, and stochastic approximation were used for parameter identification and a certainty equivalence adaptive control for the system, that is, using the current estimate of the parameters as the true parameters to verify self-optimality. An important development in stochastic adaptive control is a result called the self-tuning regulator where the convergence of estimators of unknown parameters implied the convergence of the output tracking error (Astrom and Wittenmark 1973; Goodwin et al. 1981; Guo 1995, 1996; Guo and Chen 1991; Kumar 1990).

A number of monographs treat various aspects of stochastic adaptive control problems, e.g., Astrom and Wittenmark (1989), Chen and Guo (1991), Kumar and Varaiya (1986), and Ljung and Soderstrom (1983). An extensive survey article on the early years of stochastic adaptive control is given by Kumar (1985).

Structures and Approaches

Various requirements can be made for the adaptive control of a stochastic system. It can only be required that the family of adaptive controls is stabilizing the unknown system or that the family of adaptive controls converges to the optimal control for the true system or that the family of adaptive controls has a long-run average cost that is equal to the optimal average cost for the true system. The identification part of the adaptive control problem can be Bayesian estimation (Kumar 1990) if the parameters are assumed to be random variables or parameter estimation (Bercu 1995; Lai and Wei 1982) if the parameters are assumed to be unknown constants. The identification scheme may also incorporate information about the running cost.

For linear systems with white noise inputs, it is well known to use least squares (or equivalently maximum likelihood) estimation to estimate parameters. However, for stochastic adaptive control problems, the sufficient conditions for the family of estimators to be strongly consistent are fairly restrictive (e.g., Lai and Wei 1982), and in fact the family of estimators may not even converge in general. A weighted least squares estimation scheme can guarantee convergence of the family of estimators (Bercu 1995) and can often be strongly consistent (Guo 1996). Some other estimation methods are stochastic approximation (Guo and Chen 1991) and an ordinary differential equation approach (Ljung and Soderstrom 1983). For discrete-time nonlinear systems, a family of strongly consistent estimators may not converge sufficiently rapidly even to stabilize the nonlinear system (Guo 1997).

The study of stochastic adaptive control of continuous-time linear stochastic systems with long-run average quadratic costs developed somewhat after the corresponding discrete-time study (e.g., Duncan and Pasik-Duncan 1990). A solution with basically the natural assumptions from the solution of the known system problem using a weighted least squares identification scheme is given in Duncan et al. (1999).

Another family of stochastic adaptive control problems is described by linear stochastic equations in an infinite dimensional Hilbert space. These models can describe stochastic partial differential equations and stochastic hereditary differential equations. Some linear-quadratic-Gaussian control problems have been solved, and these solutions have been used to solve some corresponding stochastic adaptive control problems (e.g., Duncan et al. 1994a).

Optimal control methods such as Hamilton-Jacobi-Bellman equations and a stochastic maximum principle have been used to solve stochastic control problems described by nonlinear stochastic differential equations (Fleming and Rishel 1975). Thus, it was natural to consider stochastic adaptive control problems for these systems. The results are more limited than the results for linear stochastic systems (e.g., Duncan et al. 1994b).

Other stochastic adaptive control problems have recently emerged that are modeled by multi-agents, such as mean field stochastic adaptive control problems (e.g., Nourian et al. 2012).

A Detailed Example: Adaptive Linear-Quadratic-Gaussian Control

This example is a model that is the most well known continuous-time stochastic adaptive control problem. Likewise for a known continuous-time system, this stochastic control problem is the most basic and well known. The controlled system is described by the following stochastic differential equation:

$$dX(t) = AX(t)dt + BU(t)dt + CdW(t)$$
$$X(0) = X_0$$

where $X(t) \in \mathbb{R}^n, U(t) \in \mathbb{R}^m$, and $(W(t), t \geq 0)$ is an $\mathbb{R}^p$-valued standard Brownian motion and (A, B, C) are appropriate linear transformations. $X(t)$ is the state of the system at time t and $U(t)$ is the control at time t. It is assumed that A, B, C are unknown linear transformations. The cost functional, $J(\cdot)$, is a long-run average (ergodic) quadratic cost functional that is given by

$$J(U) = \lim \sup_{T \to \infty} \frac{1}{T} \int_0^T < QX(t), X(t) >$$
$$+ < RU(t), U(t) > dt$$

where $R > 0$ and $Q \geq 0$ are symmetric linear transformations and $< \cdot, \cdot >$ is the canonical inner product in the appropriate Euclidean space. The standard assumptions for the control of the known system are made also for the adaptive control problem, that is, the pair (A, B) is controllable and $(A, Q^{\frac{1}{2}})$ is observable. An optimal control for the known system is

$$U^0(t) = -R^{-1}B^T S X(t)$$

where S is the unique positive, symmetric solution of the following algebraic Riccati equation:

$$A^T S + SA - SBR^{-1}B^T S + Q = 0$$

The optimal cost is

$$J(U^0) = tr(C^T S C)$$

The unknown quantity $C^T C$ can be identified given $(X(t), t \in [a, b])$ for $a < b$ arbitrary from the quadratic variation of Brownian motion, so the identification of C is not considered here. Since it is assumed that the pair (A, B) is unknown, the system equation is rewritten in the following form:

$$dX(t) = \theta^T \varphi(t)dt + C dW(t)$$

where $\theta^T = [A \; B]$ and $\varphi^T(t) = [X^T(t) \; U^T(t)]$. A family of continuous-time weighted least squares recursive estimators $(\theta(t), t \geq 0)$ of θ is given by the following stochastic equation:

$$d\theta(t) = a(t)P(t)\varphi(t)[dX^T(t) - \varphi^T(t)\theta(t)dt]$$
$$dP(t) = -a(t)P(t)\varphi(t)\varphi^T(t)P(t)dt$$

where $(a(t), t \geq 0)$ is a suitable family of positive stochastic weights (Duncan et al. 1999). A family of estimates $(\hat{\theta}(t), t \geq 0)$ is obtained from $(\theta(t), t \geq 0)$ and is expressed as $\hat{\theta}(t) = [A(t) \; B(t)]$ (Duncan et al. 1999).

A process $(S(t), t \geq 0)$ is obtained using $(A(t), B(t))$ by solving the following stochastic algebraic Riccati equation for each $t \geq 0$:

$$A^T(t)S(t) + S(t)A(t)$$
$$- S(t)B(t)R^{-1}B^T(t)S(t) + Q = 0$$

A certainty equivalence method is used to determine the control, that is, it is assumed that the pair $(A(t), B(t))$ is the correct pair for the true system, so a certainty equivalence adaptive control $U(t)$ is given by

$$U(t) = R^{-1}B^T S(t) X(t)$$

It can be shown (Duncan et al. 1999) that the family of estimators $((A(t), B(t)), t \geq 0)$ is strongly consistent and that the family of adaptive controls given by the previous equality is self-optimizing, that is, the long-run average cost $J(U) = J(U^0) = tr(C^T S C)$ where S is the solution of the algebraic Riccati equation for the true system.

Future Directions

A number of important directions for stochastic adaptive control are easily identified. Only three of them are described briefly here. The adaptive control of the partially observed linear-quadratic-Gaussian control problem (Fleming and Rishel 1975) is a major problem to be solved using the same assumptions of controllability and observability as for the known system. This problem is a generalization of the example given above where the output (linear transformation) of the system is observed with additive noise and the family of controls is restricted to depend only on these observations. Another major direction is to modify the detailed example above by replacing the Brownian motion in the stochastic equation for the state by an arbitrary fractional Brownian motion or by an arbitrary square-integrable stochastic process with continuous sample paths. For this latter problem it is necessary to use recent results for optimal controls for the true

system and to have strongly consistent families of estimators. A third major direction is the adaptive control of nonlinear stochastic systems.

Abstract

Conventional deterministic chemical kinetics often breaks down in the small volume of a living cell where cellular species (e.g., genes, mRNAs, etc.) exist in discrete, low copy numbers and react through reaction channels whose timing and order is random. In such an environment, a stochastic chemical kinetics framework that models species abundances as discrete random variables is more suitable. The resulting models consist of continue-time discrete-state Markov chains. Here we describe how such models can be formulated and numerically simulated, and we present some of the key analysis techniques for studying such reactions.

Keywords

Chemical master equation; Gillespie algorithm; Moment dynamics; Stochastic biochemical reactions; Stochastic models

Introduction

The time evolution of a spatially homogeneous mixture of chemically reacting molecules is often modeled using a stochastic formulation, which takes into account the inherent randomness of thermal molecular motion. This formulation is important when modeling complex reactions inside living cells, where small populations of key reactants can set the stage for significant stochastic effects. In this entry, we review the basic stochastic model of chemical reactions and discuss the most common techniques used to simulate and analyze this model.

Stochastic Models of Chemical Reactions

We start by considering a set of N molecular species (reactants) $\mathcal{S}_1, \ldots, \mathcal{S}_N$ that are confined to a fixed volume Ω. These species react through M possible reactions $R_1, \ldots, R_M$. In this formulation of chemical kinetics, we shall assume that the system is in thermal equilibrium and is well mixed. Thus, the reacting molecules move due to their thermal energy. The population of the different reactants is described by a random process $X(t) = (X_1(t) \ldots X_N(t))^T$, where $X_i(t)$ is a random variable that models the abundance (in terms of the number of copies) of molecules of species $\mathcal{S}_i$ in the system at time t. For the allowable reactions, we shall only consider elementary reactions. These could either be monomolecular, $\mathcal{S}_i \rightarrow$ products, or bimolecular, $\mathcal{S}_i + \mathcal{S}_j \rightarrow$ products. Upon the firing of reaction R_k, a transition occurs from some state $X = x_i$ right before the reaction fires to some other state $X = x_i + s_k$, which reflects the change in the population immediately after the reaction has fired. s_k is referred to as the *stoichiometric vector*. The set

Stochastic Description of Biochemical Networks, Table 1 Propensity functions for elementary reactions. The constants c, c', and c'' are related to k, k', and k'', the reaction rate constants from *deterministic* mass-action kinetics. Indeed it can be shown that $c = k$, $c' = k'/\Omega$, and $c'' = 2k''/\Omega$

Reaction type	Propensity function
$S_i \rightarrow$ Products	$c x_i$
$S_i + S_j \rightarrow$ Products $\quad (i \neq j)$	$c' x_i x_j$
$S_i + S_i \rightarrow$ Products	$c'' x_i (x_i - 1)/2$

of allowable M reactions defines the so-called stoichiometry matrix:

$$S = \begin{bmatrix} s_1 \cdots s_M \end{bmatrix}.$$

To each reaction R_k, we associate a *propensity function*, $w_k(x)$ that describes the rate of that reaction. More precisely, $w_k(x)h$ is the probability that, given the system is in state x at time t, R_k fires once in the time interval $[t, t + h)$. The propensity functions for elementary reactions is given in Table 1.

Limiting to the Deterministic Regime

There is an important connection between the stochastic process $X(t)$, as represented by the continuous-time discrete-state Markov chain described above, and the solution of a related deterministic reaction rate equations obtained from mass-action kinetics. To see this, let $\Phi(t) = [\Phi_1(t), \ldots, \Phi_N(t)]^T$ be the vector concentrations of species $S_1, \ldots, S_N$. According to mass-action kinetics, $\Phi(\cdot)$ satisfies the ordinary differential equation:

$$\dot{\Phi} = S f(\Phi(t)), \qquad \Phi(0) = \Phi_0.$$

In order to compare the $\Phi(t)$ with $X(t)$, which represents molecular counts, we divide $X(t)$ by the reaction volume to get $X^\Omega(t) = X(t)/\Omega$. It turns out that $X^\Omega(t)$ *limits* to $\Phi(t)$: According to Kurtz (Ethier and Kurtz 1986), for every $t \geq 0$:

$$\lim_{\Omega \rightarrow \infty} \sup_{s \leq t} \left| X^\Omega(s) - \Phi(s) \right| = 0, \quad \text{almost surely.}$$

S

Hence, over any finite time interval, the stochastic model *converges* to the deterministic mass-action one in the thermodynamic limit. Note that this is only a large volume limit result. In practice, for a fixed volume, a stochastic description may differ considerably from the deterministic description.

Stochastic Simulations

Gillespie's stochastic simulation algorithm (SSA) constructs sample paths for the random process $X(t) = (X_1(t) \ldots . X_N(t))^T$ that are consistent with the stochastic model described above (Gillespie 1976). It consists of the following basic steps:

1. Initialize the state $X(0)$ and set $t = 0$.
2. Draw a random number $\tau \in (0, \infty)$ with exponential distribution and mean equal to $1/ \sum_k w_k(X(t))$.
3. Draw a random number $k \in \{1, 2, \ldots, M\}$ such that the probability of $k = i \in \{1, 2, \ldots, M\}$ is proportional to $w_i(X(t))$.
4. Set $X(t + \tau) = X(t) + s_k$ and $t = t + \tau$.
5. Repeat from (2) until t reaches the desired simulation time.

By running this algorithm multiple times with independent random draws, one can estimate the distribution and statistical moments of the random process $X(t)$.

The Chemical Master Equation (CME)

The *chemical master equation* (CME), also known as the forward Kolmogorov equation, describes the time evolution of the probability that the system is in a given state x. The CME can be derived based on the Markov property of chemical reactions. Suppose the system is in state x at time t. Within an error of order $\mathcal{O}(h^2)$, the following statements apply:

- The probability that an R_k reaction fires exactly once in the time interval $[t, t+h]$ is given by $w_k(x)h$.
- The probability that no reactions fire in the time interval $[t, t + h)$ is given by $1 - \sum_k w_k(x)dx$.

- The probability that more than one reaction fires in the time interval $[t, t + h)$ is zero.

Let $P(x, t)$, denote the probability that the system is in state x at time t. We can express $P(x, t + h)$ as follows:

$$P(x, t + h) = P(x, t) \left(1 - \sum_k w_k(x)h\right)$$
$$+ \sum_k P(x - s_k, t)w_k(x - s_k)h + \mathcal{O}(h^2).$$

The first term on the right-hand side is the probability that the system is already in state x at time t, and no reactions occur in the next h. In the second term on the right-hand side, the kth term in the summation is the probability that the system at time t is an R_k reaction away from being at state x and that an R_k reaction takes place in the next h.

Moving $P(x, t)$ to the left-hand side, dividing by h, and taking the limit as h goes to zero yields the chemical master equation (CME):

$$\frac{dP(x, t)}{dt} = \sum_{k=1}^M \Big(w_k(x - s_k)P(x - s_k, t) - w_k(x)P(x, t)\Big). \quad (1)$$

The CME defines a linear dynamical system in the probabilities of the different states (each state is defined by a specific number of molecules of each of the species). However, there are generally an infinite number of states, and the resulting infinite linear system is not directly solvable. One approach to overcome this difficulty is to approximate the solution of the CME by truncating the states. A particular truncation procedure that gives error bounds is called the finite-state projection (FSP) (Munsky and Khammash 2006). The key idea behind the FSP approach is to keep those states that support the bulk of the probability distribution while projecting the remaining infinite states onto a single "absorbing" state. See Fig. 1.

The left panel in the figure shows the infinite states of a system with two species. The arrows indicate transitions among states caused
Stochastic Description of Biochemical Networks, Fig. 1 The finite-state projection

by allowable chemical reactions. The underlying stochastic process is a continuous-time discrete-state Markov process. The right panel shows the projected (finite-state) system for a specific projection region (box). The projection is obtained as follows: transitions within the retained sates are kept, while transitions that emanate from these states and end at states outside the box are channeled to a single new absorbing state. Transitions into the box are deleted. The resulting projected system is a finite-state Markov process. The probability of each of its finite states can be computed exactly. It can be shown that the truncation, as defined here, gives a lower bound for the probability for the original full system. The FSP algorithm provides a way for constructing an approximation of the CME that satisfies any prespecified accuracy requirement.

Moment Dynamics

While the probability distribution $P(x, t)$ provides great detail on the state x at time t, often statistical moments of the molecule copy numbers already provide important information about their variability, which motivates the construction

of mathematical models for the evolution of such models over time.

Given a vector of integers $m := (m_1, m_2, \ldots, m_n)$, we use the notation $\mu^{(m)}$ to denote the following uncentered moment of X:

$$\mu^{(m)} := \mathrm{E}[X_1^{m_1} X_2^{m_2} \cdots X_n^{m_n}].$$

Such moment is said to be of order $\sum_i m_i$. With N species, there are exactly N first-order moments $\mathrm{e}[X_i]$, $\forall i \in \{1, 2, \ldots, N\}$, which are just the means; $N(N-1)/2$ second-order moments $\mathrm{e}[X_i^2]$, $\forall i$ and $\mathrm{e}[X_i X_j]$, $\forall i \neq j$, which can be used to compute variances and covariance; $N(N-1)(N-2)/6$ third-order moments; and so on.

Using the CME (1), one can show that

$$\frac{d\mu^{(m)}}{dt} = \mathrm{E}\Big[\sum_k w_k(X) \Big((X_1 + s_{1,k})^{m_1} (X_2 - s_{2,k})^{m_2}$$
$$\cdots (X_N - s_{N,k})^{m_N} - X_1^{m_1} X_2^{m_2} \cdots X_N^{m_N} \Big) \Big],$$

and, because the propensity functions are all polynomials on x (cf. Table 1), the expected value in the right-hand side can actually be written as a linear combination of other uncentered moments of X. This means that if we construct a

vector μ containing all the uncentered moments of x up to some order k, the evolution of μ is determined by a differential equation of the form

$$\frac{d\mu}{dt} = A\mu + B\bar{\mu}, \quad \mu \in \mathbb{R}^K, \ \bar{\mu} \in \mathbb{R}^{\bar{K}} \quad (2)$$

where A and B are appropriately defined matrices and $\bar{\mu}$ is a vector containing moments of order larger than k. The equation (2) is exact, and we call it the *(exact) k-order moment dynamics*, and the integer k is called the *order of truncation*. Note that the dimension K of (2) is always larger than k since there are many moments of each order. In fact, in general, K is of order n^k.

When all chemical reactions have only one reactant, the term $B\bar{\mu}$ does not appear in (2), and we say that the exact moment dynamics are *closed*. However, when at least one chemical reaction has two or more reactants, then the term $B\bar{\mu}$ appears, and we say that the moment dynamics are *open* since (2) depends on the moments in $\bar{\mu}$, which are not part of the state μ. When all chemical reactions are elementary (i.e., with at most two reactants), then all moments in $\bar{\mu}$ are exactly of order $k + 1$.

Moment closure is a procedure by which one approximates the exact (but open) moment dynamics (2) by an approximate (but now closed) equation of the form

$$\dot{v} = Av + B\varphi(v), \quad v \in \mathbb{R}^K \quad (3)$$

where $\varphi(v)$ is a column vector that approximates the moments in $\bar{\mu}$. The function $\varphi(v)$ is called the moment closure function, and (3) is called the *approximate kth-order moment dynamics*. The goal of any moment closure method is to construct $\varphi(v)$ so that the solution v to (3) is close to the solution μ to (2).

There are three main approaches to construct the moment closure function $\varphi(\cdot)$:

1. *Matching-based methods* directly attempt to match the solutions to (2) and (3) (e.g., Singh and Hespanha 2011).
2. *Distribution-based methods* construct $\varphi(\cdot)$ by making reasonable assumptions on the statis-

tical distribution of the molecule counts vector x (e.g., Gomez-Uribe and Verghese 2007).
3. *Large volume methods* construct $\varphi(\cdot)$ by assuming that reactions take place on a large volume (e.g., Van Kampen 2001).

It is important to emphasize that this classification is about methods to *construct* moment closure. It turns out that sometimes different methods lead to the same moment closure function $\varphi(\cdot)$.

Conclusion and Outlook

We have introduced complementary approaches to study the evolution of biochemical networks that exhibit important stochastic effects.

Stochastic simulations permit the construction of sample paths for the molecule counts, which can be averaged to study the ensemble behavior of the system. This type of approach scales well with the number of molecular species, but can be computationally very intensive when the number of reactions is very large. This challenge has led to the development of approximate stochastic simulation algorithms that attempt to simulate multiple reactions in the same simulation step (e.g., Rathinam et al. 2003).

Solving the CME provides the most detailed and accurate approach to characterize the ensemble properties of the molecular counts, but for most biochemical systems such solution cannot be found in closed form, and numerical methods scale exponentially with the number of species. This challenge has led to the development of algorithms that compute approximate solutions to the CME, e.g., by aggregating states with low probability, while keeping track of the error (e.g., Munsky and Khammash 2006).

Moment dynamics is attractive in that the number of kth-order moments only scales polynomially with the number of chemical species, but one only obtains closed dynamics for very simple biochemical networks. This limitation has led to the development of moment closure techniques to approximate the open moment dynamics by a closed system of ordinary differential equations.

Abstract

This article is concerned with one of the traditional approaches for stochastic control problems: Stochastic dynamic programming. Brief descriptions of stochastic dynamic programming methods and related terminology are provided. Two asset-selling examples are presented to illustrate the basic ideas. A list of topics and references are also provided for further reading.

Keywords

Introduction

The term *dynamic programming* was introduced by Richard Bellman in the 1940s. It refers to a method for solving dynamic optimization problems by breaking them down into smaller and simpler subproblems.

To solve a given problem, one often needs to solve each part of the problem (subproblems) and then put together their solutions to obtain an overall solution. Some of these subproblems are of the same type. The idea behind the dynamic programming approach is to solve each subproblem only once in order to reduce the overall computation.

The cornerstone of dynamic programming (DP) is the so-called principle of optimality which is described by Bellman in his 1957 book (Bellman 1957):

> Principle of Optimality: An optimal policy has the property that whatever the initial state and initial decision are, the remaining decisions must constitute an optimal policy with regard to the state resulting from the first decision.

This principle of optimality gives rise to DP (or optimality) equations, which are referred to as Bellman equations in discrete-time optimization problems or Hamilton-Jacobi-Bellman (HJB) equations in continuous-time ones. Such equations provide a necessary condition for optimality in terms of the value of the underlying decision problem. By and large, an optimal control policy in most cases can be obtained by solving the associated Bellman (HJB) equation. In view of this, dynamic programming is a powerful tool for a broad range of control and decision-making problems. When the underlying system is driven by certain type of random

S

disturbance, the corresponding DP approach is referred to as *stochastic dynamic programming*.

Terminology

The following concepts are often used in stochastic dynamic programming.

An **objective function** describes the objective of a given optimization problem (e.g., maximizing profits, minimizing cost, etc.) in terms of the states of the underlying system, decision (control) variables, and possible random disturbance.

State variables represent the information about the current system under consideration. For example, in a manufacturing system, one needs to know the current product inventory in order to decide how much to produce at the moment. In this case, the inventory level would be one of the state variables.

The variables chosen at any time are called the decision or **control variables**. For instance, the rate of production over time in the manufacturing system is a control variable. Typically, control variables are functions of state variables. They affect the future states of the system and the objective function.

In stochastic control problems, the system is also affected by random events (noise). Such noise is referred to system **disturbance**. The noise is often not available a priori. Only their probabilistic distributions are known.

The goal of the optimization problem is to choose control variables over time so as to either maximize or minimize the corresponding objective function. For example, in order to maximize the overall profits, a manufacturing firm has to decide how much to produce over time so as to maximize the revenue by meeting the product demand and minimize the costs associated with inventory. The best possible value of the objective is called **value function**, which is given in terms of the state variables.

In the next two sections, we give two examples to illustrate how stochastic DP methods are used in discrete and continuous time.

An Asset-Selling Example (Discrete Time)

Consider a person wants to sell an asset (e.g., a car or a house). She is offered an amount of money every period (say, a day). Let $v_0, v_1, \ldots, v_{N-1}$ denote the amount of these random offers. Assume they are independent and identically distributed. At the end of each period, the person has to decide whether to accept the offer or reject it. If she accepts the offer, she can put the money in a bank account and receive a fixed interest rate $r > 0$; if she rejects the offer, she waits till the next period. Rejected offers cannot be recycled. In addition, she has to sell her asset by the end of the Nth period and accept the last offer v_{N-1} if all previous offers have been rejected. The goal is to decide when to accept an offer to maximize the overall return at the Nth period.

In this example, for each k, v_k is the random disturbance. The control variables u_k take values in {sell, hold}. The state variables x_k are given by the equations

$$x_0 = 0; \quad x_{k+1} = \begin{cases} \text{sold} & \text{if } u_k = \text{sell} \\ v_k & \text{otherwise.} \end{cases}$$

Let

$$h_N(x_N) = \begin{cases} x_N & \text{if } x_N \neq \text{sold,} \\ 0 & \text{otherwise.} \end{cases}$$

$$h_k(x_k, u_k, v_k) = \begin{cases} (1+r)^{N-k} x_k & \text{if } x_k \neq \text{sold} \\ & \text{and } u_k = \text{sell} \\ 0 & \text{otherwise.} \end{cases}$$

for $k = 0, 1, \ldots, N - 1$.

Then, the payoff function is given by

$$E_{\{v_k\}} \left(h_N(x_N) + \sum_{k=0}^{N-1} h_k(x_k, u_k, v_k) \right).$$

Here, $E_{\{v_k\}}$ represents the expected value over $\{v_k\}$. The corresponding value functions $V_k(x_k)$ satisfy the following Bellman equations:

$$V_N(x_N) = \begin{cases} x_N & \text{if } x_N \neq \text{sold,} \\ 0 & \text{otherwise.} \end{cases}$$

$$V_k(x_k) = \begin{cases} \max\left((1+r)^{N-k} x_k, E V_{k+1}(v_k)\right) & \text{if } x_k \neq \text{sold} \\ 0 & \text{otherwise.} \end{cases}$$

$$\text{for } k = 0, 1, \ldots, N-1.$$

The optimal selling rule can be given as (assuming $x_k \neq$ sold) (see Bertsekas 1987):

accept the offer

$$v_{k-1} = x_k \text{ if } (1+r)^{N-k} x_k \geq E V_{k+1}(v_k),$$

reject the offer

$$v_{k-1} = x_k \text{ if } (1+r)^{N-k} x_k < E V_{k+1}(v_k).$$

Given the distribution for v_k, one can compute V_k backwards and solve the Bellman equations, which in turn leads to the above optimal selling rule.

Note that such backward iteration only works with finite horizon dynamic programming. When working with an infinite horizon (discounted or long-run average) payoff function, often used methods are value iteration (successive approximation) and policy iteration. The idea is to construct a sequence of functions recursively so that they converge pointwise to the value function. For description of these iteration methods, their convergence properties, and error bound analysis, we refer the reader to Bertsekas (1987).

Next, we consider a continuous-time asset-selling problem.

An Asset-Selling Example (Continuous Time)

Suppose a person wants to sell her asset. The price x_t at time $t \in [0, \infty)$ of her asset is given by a stochastic differential equation

$$\frac{dx_t}{x_t} = \mu dt + \sigma dw_t,$$

where μ and σ are known constants and w_t is the standard Brownian motion representing the disturbance. Suppose the transaction cost is K and the discount rate r. She has to decide when to sell her asset to maximize an expected return. In this example, the state variable is price x_t, control variable is a function of selling time τ, and the payoff function is given by

$$J(x, \tau) = E e^{-r\tau} (x_\tau - K).$$

Let $V(x)$ denote the value function, i.e., $V(x) = \sup_\tau J(x, \tau)$. Then the associate HJB equation is given by

$$\min\left\{ r V(x) - x\mu \frac{dV(x)}{dx} - \frac{x^2 \sigma^2}{2} \frac{d^2 V(x)}{dx^2}, \right.$$
$$\left. V(x) - K \right\} = 0. \qquad (1)$$

Let

$$x^* = \frac{K\beta}{\beta - 1},$$

where

$$\beta = \frac{1}{\sigma^2} \left(\frac{\sigma^2}{2} - \mu + \sqrt{\left(\mu - \frac{\sigma^2}{2}\right)^2 + 2r\sigma^2} \right).$$

Then the optimal selling rule can be given as (see Øksendal 2007):

$$\begin{cases} \text{sell} & \text{if } x_t \geq x^*, \\ \text{hold} & \text{if } x_t < x^*. \end{cases}$$

In general, to solve an optimal control problem via the DP approach, one first needs to solve the associate Bellman (HJB) equations. Then, these

S

solutions can be used to come up with an optimal control policy. For example, in the above case, given the value function $V(x)$, one should hold if

$$rV(x) - x\mu \frac{dV(x)}{dx} - \frac{x^2\sigma^2}{2}\frac{d^2V(x)}{dx^2} = 0$$

and sell when $V(x) - K = 0$. The threshold level x^* is the exact dividing point between the first part equals zero and the second part vanishes. In addition, one can also provide a theoretical justification in terms of a verification theorem to show that the solution obtained this way is indeed optimal (see Fleming and Rishel (1975), Fleming and Soner (2006), or Yong and Zhou (1999)).

HJB Equation Characterization and Computational Methods

In continuous-time optimal control problem, one major difficulty that arises in solving the associated HJB equations (e.g., (1)) is the characterization of the solutions. In most cases, there is no guarantee that the derivatives or partial derivatives exist. In this connection, the concept of viscosity solutions developed by Crandall and Lions in the 1980s can often be used to characterize the solutions and their uniqueness. We refer the reader to Fleming and Soner (2006) for related literature and applications. In addition, we would like to point out that closed-form solutions are rare in stochastic control theory and difficult to obtain in most cases. In many applications, one needs to resort to computational methods. One typical way to solve an HJB equation is the finite difference methods. An alternative is Kushner's Markov chain approximation methods; see Kushner and Dupuis (1992).

Summary and Future Directions

In this article, we have briefly stated stochastic DP methods, showed how they work in two simple examples, and discussed related issues. One serious limitation of the DP approach is the so-called curse of dimensionality. In other words, the DP does not work for problems with high dimensionality. Various efforts have been devoted to search for approximate solutions. One approach developed in recent years is the multi-time-scale approach. The idea is to classify random events according to the frequency of their occurrence. Frequent occurring events are grouped together and treated as a single "state" to achieve the reduction of dimensionality. We refer the reader to Yin and Zhang (2005, 2013) for related literature and theoretical development. Finally, we would like to mention that stochastic DP has been used in many applications in economics, engineering, management science, and finance. Some applications can be found in Sethi and Thompson (2000). Additional references are also provided at the end for further reading.

Abstract

A stochastic game was introduced by Lloyd Shapley in the early 1950s. It is a dynamic game with *probabilistic transitions* played by one or more players. The game is played in a sequence of stages. At the beginning of each stage, the game is in a certain *state*. The players select actions, and each player receives a *payoff* that depends on the current state and the chosen actions. The game then moves to a new random state whose distribution depends on the previous state and the actions chosen by the players. The procedure is repeated at the new state, and the play continues for a finite or infinite number of stages. The total payoff to a player is often taken to be the discounted sum of the stage payoffs
or the limit inferior of the averages of the stage payoffs.

A learning problem arises when the agent does not know the reward function or the state transition probabilities. If an agent directly learns about its optimal policy without knowing either the reward function or the state transition function, such an approach is called *model-free reinforcement learning*. Q-learning is an example of such a model.

Q-learning has been extended to a noncooperative multi-agent context, using the framework of general-sum stochastic games. A learning agent maintains Q-functions over joint actions and performs updates based on assuming Nash equilibrium behavior over the current Q-values. The challenge is convergence of the learning protocol.

Keywords

Introduction

A Stochastic Game

Definition 1 (Stochastic games) A stochastic game is a dynamic game with probabilistic transitions played by one or more players. The game is played in a sequence of stages. At the beginning of each stage, the game is in a certain state. The players select *actions*, and each player receives *a payoff* that depends on the current state and the chosen actions. The game then moves to a new random state whose distribution depends on the previous state and the actions chosen by the players. The process is repeated at the new state, and the play continues for a finite or infinite number of stages.

The total payoff to a player can be defined in various ways. It depends on the payoffs at each stage and strategies chosen by players. The aim of the players is to control their total payoffs in the game by appropriate actions.

S

The notion of a stochastic game was introduced by Lloyd Shapley (1953) in the early 1950s. Stochastic games generalize both Markov decision processes (see also MDP) and repeated games. A repeated game is equivalent to a stochastic game with a single state. The stochastic game is played in discrete time with past history as common knowledge for all the players. An *individual strategy* for a player is a map which associates with each given history a probability distribution on the set of actions available to the players. The players' actions at stage n determines the players' payoffs at this stage and the state $s \in \mathfrak{S}$ at stage $n + 1$.

Learning

Learning is acquiring new, or modifying and reinforcing existing, knowledge, behaviors, skills, values, or preferences, and may involve synthesizing different types of information. The ability to learn is possessed by humans, animals, and some machines which will be later called *agents*. In the context of this entry, learning refers to a particular class of stochastic game theoretical models.

Definition 2 (Learning in stochastic games) A learning problem arises when an agent does not know the reward function or the state transition probabilities. If the agent directly learns about its optimal policy without knowing either the reward function or the state transition function, such an approach is called *model-free reinforcement learning*. Q-learning is an example of such a model.

Learning models constitute a branch of larger literature. Players follow a form of behavioral rule, such as imitation, regret minimization, or reinforcement. Learning models are most appropriate in settings where players have a good understanding of their strategic environment and where the stakes are high enough to make forecasting and optimization worthwhile. The known approaches are formulated as *minimax-Q* (Littman 1994), Nash-Q (Hu and Wellman 1998), tinkering with learning rates ("Win or Learn Fast"-WoLF, Bowling and Veloso 2001) and multiple timescale Q-learning (Leslie and Collins 2005).

Model of Stochastic Game

Let us assume that the environment is modeled by the probability space $(\Omega, \mathcal{F}, \mathbf{P})$. An N-*person stochastic game* is described by the objects $(\mathfrak{N}, \mathfrak{S}, X_k, A_k, r_k, q)$ with the interpretation that:

1. $\mathfrak{N}$ is a set of players, with $|\mathfrak{N}| = N \in \mathbb{N}$.
2. $\mathfrak{S}$ is the *set of states* of the game, and it is finite.
3. $\overrightarrow{X} = X_1 \times X_2 \times \ldots \times X_N$ is the *state of actions*, where X_k is a nonempty, finite space of actions for player k.
4. A_k's are correspondences from $\mathfrak{S}$ into nonempty subsets of X_k. For each $s \in \mathfrak{S}$, $A_k(s)$ represents the *set of actions* available to player k in state s. For $s \in \mathfrak{S}$, denote $\overrightarrow{A}(s) = A_1(s) \times A_2(s) \times \ldots \times A_N(s)$.
5. $r_k : \mathfrak{S} \times \overrightarrow{X} \to \mathfrak{R}$ is a payoff function for player k.
6. q is a transition probability from $\mathfrak{S} \times \overrightarrow{X}$ to $\mathfrak{S}$, called the *law of motion* among states. If s is a state at a certain stage of the game and the players select $\overrightarrow{x} \in \overrightarrow{A}(s)$, then $q\left(\cdot | s, \overrightarrow{x}\right)$ is the probability distribution of the next state of the game.

The stochastic game generates two processes:
1. $\{\sigma_n\}_{n=1}^{T}$ with values in $\mathfrak{S}$
2. $\{\alpha_n\}_{n=1}^{T}$ with values in $\overrightarrow{X}$

Strategies

Let $\mathfrak{H} = \mathfrak{S}_1 \times \overrightarrow{X}_1 \times \mathfrak{S}_2 \times \cdots$ be the space of all infinite histories of the game and $\mathfrak{H}_n = \mathfrak{S}_1 \times \overrightarrow{X}_1 \times \mathfrak{S}_2 \times \overrightarrow{X}_2 \times \cdots \mathfrak{S}_n$ the histories up to stage n.

Definition 3 A player's *strategy* $\pi = \{\alpha_n\}_{n=1}^{T}$ consists of random maps $\alpha_n : \Omega \times \mathfrak{H}_n \to X$. In other words, the strategy associates with each given history a probability distribution dependent on the set of actions available to the player. If α_n is dependent on the history only, it is called deterministic.

The mathematical description of the strategies can be made as follows:
1. For player $i \in \mathbb{N}$, a deterministic strategy specifies a choice of actions for the player at every stage of every possible history.

2. A mixed strategy is a probability distribution over deterministic strategies.
3. Restricted classes of strategies:
   1. A behavioral strategy – a mixed strategy in which the mixing takes place at each history independently.
   2. A Markov strategy – a behavioral strategy such that for each time t, the distribution over actions depends only on the current state, but the distribution may be different at time t than at time $t' \neq t$.
   3. A stationary strategy – a Markov strategy in which the distribution over actions depends only on the current state (not on the time t).

The Total Payoff Types

For any profile of strategies $\pi = (\pi_1, \ldots, \pi_N)$ of the players and every initial state $s_1 = s \in \mathfrak{S}$, a probability measure P_s^π and a stochastic process $\{\sigma_n, \alpha_n\}$ are defined on $\mathfrak{H}$ in a canonical way, where the random variables σ_n and α_n describe the state and the actions chosen by the players, respectively, on the nth stage of the game. Let us define E_s^π the expectation operator with respect to the probability measure P_s^π. For each profile of strategies $\pi = (\pi_1, \ldots, \pi_N)$ and every initial state $s \in \mathfrak{S}$, the following are considered:

1. The *expected T-stage payoff* to player k, for any finite horizon T, defined as

$$\Phi_k^T(\pi)(s) = E_s^\pi \left(\sum_{n=1}^{T} r_k(\sigma_n, \alpha_n) \right)$$

2. The β-discounted expected payoff to player k, where $\beta \in (0, 1)$ is called the *discount factor*, defined as

$$\Phi_k^\beta(\pi)(s) = E_s^\pi \left(\sum_{n=1}^{\infty} \beta^{n-1} r_k(\sigma_n, \alpha_n) \right)$$

3. The *average payoff per unit time* for player k defined as

$$\Phi_k(\pi)(s) = \lim_T \sup \frac{1}{T} \Phi_k^T(\pi)(s)$$

Equilibria

Let $\pi^* = (\pi_1^*, \ldots, \pi_N^*) \in \Pi$ be a fixed profile of the players' strategies. For any strategy $\pi_k \in \Pi_k$ of player k, we write (π_{-k}^*, π_k) to denote the strategy profile obtained from π^* by replacing π_k^* with π_k.

Definition 4 (A Nash equilibrium) A strategy profile $\pi^* = (\pi_1^*, \ldots, \pi_N^*) \in \Pi$ is called a *Nash equilibrium* (in Π) for the average payoff stochastic game if no unilateral deviations from it are profitable, that is, for each $s \in S$,

$$\Phi_k(\pi^*)(s) \geq \Phi_k(\pi_{-k}^*, \pi_k)(s)$$

for every player k and any strategy π_k.

Definition 5 (An ε-Nash equilibrium) A strategy profile $\pi^* = (\pi_1^*, \ldots, \pi_N^*)$ is called an ε-*(Nash) equilibrium* of the average payoff stochastic game if for every $k \in \mathfrak{N}$, we have

$$\Phi_k(\pi^*)(s) \geq \Phi_k(\pi_{-k}^*, \pi_k)(s) - \epsilon,$$

for the given $\varepsilon > 0$ and all π_k.

Nash equilibria and ε-Nash equilibria are analogously defined for the T-stage stochastic games, β-discounted stochastic games, and the average payoff per unit time stochastic games.

Construction of an Equilibrium

For stochastic games with a finite state space and finite action spaces, the existence of a stationary equilibrium has been shown (cf. Herings and Peeters 2004). The stationary strategies at time t do not depend on the entire history of the game up to that time. This allows reduction of the problem of finding discounted stationary equilibria in a general n-person stochastic game to that of finding a global minimum in a nonlinear program with linear constraints. Solving this nonlinear program is equivalent to solving a certain nonlinear system for which it is known that the objective value in the global minimum is zero (cf. Filar et al. 1991). However, as is noted by Breton (1991), the convergence of an optimization algorithm to the global optimum is not guaranteed.

S

The solution of the finite horizon finite stochastic game can be construct by dynamic programming (see, e.g., Nowak and Szajowski 1998; Tijms 2012). For discounted games, the solution construction is based on an equivalence (the two-person case is presented here for simplicity):

1. $\left(\pi_1^*, \pi_2^*\right)$ is an equilibrium point in the discounted stochastic game with equilibrium payoffs $\left(\Phi_1^\beta\left(\overrightarrow{\pi}^*\right), \Phi_2^\beta\left(\overrightarrow{\pi}^*\right)\right)$.

2. For each $s \in \mathfrak{S}$, the pair $\left(\pi_1^*(s), \pi_2^*(s)\right)$ constitutes an equilibrium point in the static bimatrix game $(B_1(s), B_2(s))$ with equilibrium payoffs $\left(\Phi_1^\beta\left(s, \overrightarrow{\pi}^*\right), \Phi_2^\beta\left(s, \overrightarrow{\pi}^*\right)\right)$, where for players $k = 1, 2$, and pure actions $(a_1, a_2) \in A_1(s) \times A_2(s)$, an admissible action space at state s, the elements of $B_k(s)$ related to (a_1, a_2)

$$
\begin{aligned}
b_k(s, a_1, a_2) := &(1 - \beta) r_k(s, a_1, a_2) \\
&+ \beta E_s^{(a_1, a_2)} \Phi_k^\beta\left(\overrightarrow{\pi}^*\right)
\end{aligned} \quad (1)
$$

An algorithm for recursive computation of stationary equilibria in stochastic games can be derived from (1). It starts with bimatrix games with $\beta = 0$, and then a careful equilibrium selection process guarantees its convergence under mild assumptions on the model (see, e.g., Herings and Peeters 2004).

A Brief History of the Research on Stochastic Games

The notion of a stochastic game was introduced by Shapley (1953) in the early 1950s. It is a dynamic game with *probabilistic transitions* played by one or more players. The game is played in a sequence of stages. At the beginning of each stage, the game is in a certain *state*. The players select actions, and each player receives a *payoff* that depends on the current state and the chosen actions. The game then moves to a new random state whose distribution depends on the previous state and the actions chosen by the players. The process is repeated at the new state, and the play continues for a finite or an infinite number of stages. The total payoff to a player is often taken to be the discounted sum of the stage

payoffs or the limit inferior of the averages of the stage payoffs.

The theory of nonzero-sum stochastic games with the average payoffs per unit time for the players started with the papers by Rogers (1969) and Sobel (1971). They considered finite state spaces only and assumed that the transition probability matrices induced by any stationary strategies of the players are irreducible. Until now, only special classes of nonzero-sum average payoff stochastic games have been shown to possess Nash equilibria (or ε-equilibria). A review of various cases and results for generalization to infinite state spaces can be found in the survey paper by Nowak and Szajowski (1998).

Learning in Stochastic Game

The problem of an agent learning to act in an unknown world is both challenging and interesting. Reinforcement learning has been successful at finding optimal control policies for a single agent operating in a stationary environment, specifically a Markov decision process. Learning to act in multi-agent systems offers additional challenges (see the following surveys: Shoham and Leyton-Brown 2009, Chap. 7; Weiß and Sen 1996; Buşoniu et al. 2010). We provide here, an overview of a general idea of learning for single and multi-agent systems:

1. Goals of single-agent reinforcement learning are to determine the optimal value and a control policy which maximizes the payoff. The model of such a system can be built based on the framework of Markov decision processes with discounted payoff. Suppose the policy is stationary and defined by a function $h : \mathfrak{S} \to X$. Such a policy defines what action should be taken in each state: $\alpha_n(\cdot) := h(\cdot)$. There are various ways to learn the optimal policy. The most straightforward way is based on the Q-values: $Q^h(s, a) = \sum_{j=0}^{\infty} \beta_{j+1}^{jr}$. The greedy action is $a = \arg\max_{a' \in A(s)} Q^h(s, a')$ (see the article on Q-learning in Reinforcement learning).

2. Multi-agent reinforcement learning can be employed to solve a single task, or an agent may be required to perform a task in an environment with other agents, either human, robot, or software ones. In either case, from an agent's perspective, the world is not stationary. In particular, the behavior of the other agents may change as they also learn to better perform their tasks. This type of a multi-agent nonstationary world creates a difficult problem for learning to act in these environments. Such a nonstationary scenario can be viewed as a game with multiple players. In game theory, in the study of such problems, there is generally an underlying assumption that the players have similar adaptation and learning abilities. Therefore, the actions of each agent affect the task achievement of the other agents. It allows to build the value of the game and an equilibrium strategy profile in following steps.

Stochastic games can be seen as an extension of the single-agent Markov decision process framework to include multiple agents whose actions all impact the resulting rewards and the next state. They can also be viewed as an extension of the framework of matrix games. Such a view emphasizes the difficulty of finding the optimal behavior in stochastic games since the optimal behavior of any one agent depends on the behavior of other agents. A comprehensive study of the multi-agent learning techniques for stochastic games does not yet exist. For the interested reader, there are monographs by Fudenberg and Levine (1998) and Shoham and Leyton-Brown (2009) and the special issue of the journal *Artificial Intelligence* (Vohra and Wellman 2007), which could be consulted.

Despite its interesting properties, Q-learning is a very slow method that requires a long period of training for learning an acceptable policy. In practice, to reduce the problem, there are parallel computing implementation models of Q-learning.

Summary and Future Directions

Details concerning solution concepts for stochastic games can be found in Filar and Vrieze (1997).

The refinements of the Nash equilibrium concept have been known in the economic dynamic games (see Myerson 1978). The Nash equilibrium concept may be extended gradually when the rules of the game are interpreted in a broader sense, so as to allow preplay or even intraplay communication. A well-known extension of the Nash equilibrium is Aumann's correlated equilibrium (see Aumann 1987), which depends only on the normal form of the game. Two other solution concepts for multistage games have been proposed by Forges (1986): the extensive form correlated equilibrium, where the players can observe private exogenous signals at every stage, and the communication equilibrium, where the players are furthermore allowed to transmit inputs to an appropriate device at every stage. An application of the notion of correlated equilibria for stochastic games can be found in Nowak and Szajowski (1998).

In economics, in the context of economic growth problems, Ramsey (1928) has introduced an *overtaking optimality* and independently (Rubinstein 1979) for repeated games. The criterion has been investigated for some stochastic games by Carlson and Haurie (1995) and Nowak (2008), and others. The existence of overtaking optimal strategies is a subtle issue, and there are counterexamples showing that one has to be careful with making statements on overtaking optimality.

Regarding a stochastic game and learning, let us mention that the first idea can be found in the papers by Brown (1951) and Robinson (1951). Some convergence results for a fictitious play have been given by Shoham and Leyton-Brown (2009) in Theorem 7.2.5. An important example showing non-convergence was given by Shapley (1964). In multi-person stochastic games and learning, convergence to equilibria is a basic stability requirement (see, e.g., Greenwald and Hall 2003; Hu and Wellman 2003). This means that the agents' strategies should eventually converge to a coordinated equilibrium. Nash equilibrium is most frequently used, but their usefulness is suspected. For instance, in Shoham and Leyton-Brown (2009), there is an argument that the link between stage-wise convergence to

S

Nash equilibria and the performance in stochastic games is unclear.

Stochastic Linear-Quadratic Control

Shanjian Tang
Fudan University, Shanghai, China

Abstract

In this short article, we briefly review some major historical studies and recent progress on continuous-time stochastic linear-quadratic (SLQ) control and related mean-variance (MV) hedging.

Keywords

Bellman's quasilinearization; BMO-martingale; Mean-variance hedging; Monotone convergence; Quadratic backward stochastic differential equations; Riccati equation

Introduction

A stochastic linear-quadratic (SLQ) control problem is the optimal control of a linear stochastic dynamic equation subject to an expected quadratic cost functional of the system state and control. As shown in Athans (1971), it is a typical case of optimal stochastic control both in theory and application. Due to the linearity of the system dynamics and the quadratic feature of the cost functions, the optimal control law is usually synthesized into a feedback (also called closed) form of the optimal state, and the corresponding proportional coefficients are specified by the associated Riccati equation. In what follows, we restrict our exposition within the continuous-time SLQ problem, and further, mainly for the finite-horizon case.

The initial study on the continuous-time SLQ problem seems to be due to Florentin (1961). However, his linear stochastic control system is assumed to be Gaussian. That is, the system noise is additive and has neither multiplication with the state nor with the control. Such a case is usually

termed as the linear-quadratic Gaussian (LQG) problem, and in the case of complete observation, the optimal feedback law remains to be invariant when the white noise vanishes. The continuous-time partially observable case was first discussed by Potter (1964) and a more general formulation was later given by Wonham (1968a). It is proved that the optimal control can be obtained by the following two separate steps: (1) generate the conditional mean estimate of the current state using a Kalman filter and (2) optimally feed back as if the conditional mean state estimate was the true state of the system. This result is referred to as the certainty equivalence principle or the strict separation theorem. Different assumptions were discussed by Tse (1971) for the separation of control and state estimation.

Wonham (1967, 1968b, 1970) investigated the SLQ problem in a fairly general systematic framework. In the first two papers, his stochastic system is able to admit a state-dependent noise. Finally, Wonham (1970) considered the following very general (admitting both state- and control-dependent noise) linear stochastic differential system driven by a d-dimensional Brownian motion $W = (W^1, W^2, \cdots, W^d)$:

$$
X_t = x + \int_0^t (A_s X_s + B_s u_s)\, dt
$$
$$
+ \int_0^t \sum_{i=1}^d (C_s^i X_s + D_s^i u_s)\, dW_s^i, \;\; t \in [0, T];
$$

and the following cost functional:

$$
J(u) = E\langle M X_T, X_T \rangle
$$
$$
+ E \int_0^T [\langle Q_t X_t, X_t \rangle + \langle N_t u_t, u_t \rangle]\, dt.
$$

Here, $T > 0$, $X_t \in R^n$ is the state at time t, and $u_t \in R^m$ is the control at time t. Assume that all the coefficients $A, B; C^i, D^i, i = 1, 2, \ldots, d; Q, N$ are piecewisely continuous matrix-valued (of suitable dimensions) functions of time, and M, Q_t are nonnegative matrices and N_t is uniformly positive. Wonham (1970) gave the following Riccati equation:

S

$$\begin{cases} -\dot{K}_t = A_t^* K_t + K_t A_t + C_t^{i*} K_t C_t^i - \Gamma_t(K_t)(N_t + D_t^{i*} K_t D_t^i)\Gamma_t(K_t), & t \in [0, T); \\ K_T = M. \end{cases} \quad (1)$$

Here, the asterisk stands for transpose, the repeated superscripts imply summation from 1 to d, and the function Γ is defined by

$$\Gamma_t(K) := -(N_t + D_t^i K D_t^i)^{-1}(KB_t + C_t^{i*} K D_t^i)^*$$

for time $t \in [0, T]$ and any $K \in \mathscr{S}_+^n :=$ {all nonnegative $n \times n$ matrices}. This Riccati equation is a nonlinear ordinary differential equation (ODE). Since the nonlinear term $\Gamma_t(K)(N_t + D_t^{i*} K D_t^i)\Gamma_t(K)$ in the right-hand side is not uniformly Lipschitz in K in general, the standard existence and uniqueness theorem of ODEs does not directly tell whether this Riccati equation has a unique continuous solution in $\mathscr{S}_+^n$. To solve this issue, Wonham (1970) used Bellman's principle of quasilinearization and constructed the following sequence of successive linear approximating matrix-valued ODEs.

Define for $(t, K, \tilde{\Gamma}) \in [0, T] \times R^{n \times n} \times R^{m \times n}$,

$$\begin{aligned} F_t(K, \tilde{\Gamma}) := &[A_t + B_t \tilde{\Gamma}]^* K + K[A_t + B_t \tilde{\Gamma}] \\ &+ [C_t^i + D_t^i \tilde{\Gamma}]^* K[C_t^i + D_t^i \tilde{\Gamma}] \\ &+ Q_t + \tilde{\Gamma}^* N_t \tilde{\Gamma}. \end{aligned} \quad (2)$$

For $K \in \mathscr{S}_+^n$, the matrix $F_t(K, \tilde{\Gamma}) - F_t(K, \Gamma_t(K))$ is nonnegative, that is,

$$F_t(K, \tilde{\Gamma}) \geq F_t(K, \Gamma_t(K)), \quad \forall \tilde{\Gamma} \in R^{m \times n}. \quad (3)$$

Riccati equation (1) can then be written into the following form:

$$\begin{cases} -\dot{K}_t = F_t(K_t, \Gamma_t(K_t)), & t \in [0, T); \\ K_T = M. \end{cases} \quad (4)$$

The iterating linear approximations are therefore structured as follows: Set $K^0 \equiv M$ and for $l = 1, 2, \ldots,$

$$\begin{cases} -\dot{K}_t^l = F_t(K_t^l, \Gamma_t(K_t^{l-1})), & t \in [0, T); \\ K_T^l = M. \end{cases} \quad (5)$$

Using the above minimal property (3) of $F_t(K, \cdot)$ at $\Gamma_t(K)$, Wonham showed that the unique nonnegative solution K^l of ODE (5) is monotonically decreasing in the sequential number $l = 1, 2, \ldots$. Using the method of monotone convergence, the sequence of solutions $\{K^l\}$ is shown to converge to some $K \in \mathscr{S}_+^n$, which turns out to solve Riccati equation (1).

The Case of Random Coefficients and Backward Stochastic Riccati Equation

Bismut (1976, 1978) are the first studies on the SLQ problem with random coefficients. Let $\{\mathscr{F}_t, t \in [0, T]\}$ be the completed natural filtration of W. When the coefficients $A, B; C^i, D^i, i = 1, 2, \ldots, d; Q, N$ and M may be random, with $A, B; C^i, D^i, i = 1, 2, \ldots, d; Q, N$ being $\mathscr{F}_t$-adapted and essentially bounded and M being $\mathscr{F}_T$-measurable and essentially bounded, Bismut (1976, 1978) used the stochastic maximum principle for optimal control and derived the following Riccati equation:

$$\begin{cases} -dK_t = [A_t^* K_t + K_t A_t + C_t^{i*} K_t C_t^i + C_t^{i*} L_t^i + L_t^i C_t^i \\ \qquad -\Psi_t(K_t, L_t)(N_t + D_t^{i*} K_t D_t^i)\Psi_t(K_t, L_t)] \, dt - L^i \, dW_t^i, \quad t \in [0, T); \\ K_T = M \end{cases} \quad (6)$$

where the function Ψ_t for $t \in [0, T]$ is defined as follows:

$$\Psi_t(K, L) := -(N_t + D_t^i K D_t^i)^{-1}(K B_t + C_t^{i*} K D_t^i + L^i D_t^i)^*, \forall\, K \in \mathscr{S}_+^n, \forall\, L$$
$$:= (L^1, \cdots, L^d) \in (R^{n \times n})^d.$$

Peng ([1992b]) used his stochastic Hamilton-Jacobi-Bellman equation to the SLQ problem and also derived the above equation. They both established the existence and uniqueness of an adapted solution of backward stochastic Riccati equation ([6]) when the function $\Psi_t(K, L)$ does not contain L. However, Bismut used the fixed-point method, and Peng ([1992b]) used Bellman's principle of quasilinearization and the method of monotone convergence. Neither methodology works for the general case of quadratic growth in the second unknown variable L in the drift of the stochastic equation. Bismut ([1976], [1978]) and Peng ([1999]) stated the general case as an open problem. By considering the stochastic equation for the inverse of K_t, Kohlmann and Tang ([2003a]) solved some particular cases where the function $\Psi_t(K, L)$ can depend on L. Tang ([2003]) finally solved the general case, using the method of stochastic flows.

In the general case, the optimal feedback coefficient $\Psi_t(K_t, L_t)$ at time t depends on L_t in a linear manner, which is in general not essentially bounded with respect to (t, ω). Kohlmann and Tang ([2003b]) observed that the stochastic integral process $\int_0^\cdot L_t^i\, dW_t^i$ is a BMO-martingale.

Indefinite SLQ Problem

Chen ([1985]) contains a theory of singular (the control weighting matrix vanishing in the quadratic cost functional) LQG control, which is a particular type of indefinite SLQ problems. In the deterministic linear-quadratic (LQ) control theory, the well posedness (i.e., the value function is finite on $[0, T] \times R^n$) of the problem suggests that the control weighting matrix N in the quadratic cost functional be positive definite. In the stochastic case, when N_t is slightly negative,

the SLQ may still be well posed if the control could also increase the intensity of the system noise. Peng ([1992a]) used an indefinite but well-posed SLQ problem to illustrate his new second-order stochastic maximum principle. Chen et al. ([1998]) gave a deeper study on this feature of the SLQ problem. Yong and Zhou ([1999]) gave a systematic account of the progress around in the indefinite SLQ problem.

Mean-Variance Hedging

In the theory of finance, Duffie and Richardson ([1991]) introduced the SLQ control model to hedge a contingent claim in an incomplete market. Schweizer ([1992]) developed a first framework for MV hedging, and then it was extended to a very general setting in Gouriéroux et al. ([1998]). Before 2000, the martingale method was used to solve the MV hedging problem. Kohlmann and Zhou ([2000]) began to use the standard SLQ theory to derive the optimal hedging strategy for a general contingent claim in a financial market of deterministic coefficients, and such a SLQ methodology was subsequently extended to very general settings for financial markets by Kohlmann and Tang ([2002], [2003b]), Bobrovnytska and Schweizer ([2004]), and Jeanblanc et al. ([2012]). See more detailed surveys on the literature by Pham ([2000]), Schweizer ([2010]), and Jeanblanc et al. ([2012]).

Summary and Future Directions

In comparison to the continuous-time deterministic LQ theory, the continuous-time SLQ theory has the following two striking features: An indefinite SLQ problem may be well posed, and the

S

optimal feedback coefficient may be unbounded due to its linear dependence on the martingale part L of the stochastic solution of the Riccati equation. Due to the second feature, the convergence of the sequence of successive approximations constructed via Bellman's quasilinearization still remains to be solved in the general case. This problem partially motivates Delbaen and Tang (2010) to study the regularity of unbounded stochastic differential equations and also may help to explain the necessity of rich studies on mean-variance hedging and closedness of stochastic integrals with respect to semimartingales (as in Delbaen et al. 1994, 1997) in various general settings.

Abstract

The stochastic maximum principle (SMP) gives some necessary conditions for optimality for a stochastic optimal control problem. We give a summary of well-known results concerning stochastic maximum principle in finite-dimensional state space as well as some recent developments in infinite-dimensional state space.

Keywords

Introduction

The problem of finding sufficient conditions for optimality for a stochastic optimal control problem with finite-dimensional state equation had been well studied since the pioneering work of Bismut (1976, 1978). In particular, Bismut introduced linear backward stochastic differential equations (BSDEs) which have become an active domain of research since the seminal paper of Pardoux and Peng in 1990 concerning (nonlinear) BSDEs in Pardoux and Peng (1990).

The first results on SMP concerned only the stochastic systems where the control domain is convex or the diffusion coefficient does not contain control variable. In this case, only the first-order expansion is needed. This kind of SMP was developed by Bismut (1976, 1978), Kushner (1972), and Haussmann (1986). It is important to note that (Bismut 1978) introduced linear BSDE to represent the first-order adjoint process.

Peng made a breakthrough by establishing the SMP for the general stochastic optimal control problem where the control domain need not to be convex and the diffusion coefficient can contain the control variable. He solved this general case by introducing the second-order expansion and second-order BSDE. We refer to the book Yong and Zhou (1999) for the account of the theory of SMP in finite-dimensional spaces and describe Peng's SMP in the next section.

Despite the fact that the problem has been solved in complete generality more than 20 years ago, the infinite-dimensional case still has important open issues both on the side of the generality of the abstract model and on the side of its applicability to systems modeled by stochastic partial differential equations (SPDEs). The last section is devoted to the recent development of SMP in infinite-dimensional space.

S

Statement of SMP

Formulation of Problem

Let $(\Omega, \mathcal{F}, \mathbb{P})$ be a complete probability space, on which an m-dimensional Brownian motion W is given. Let $\{\mathcal{F}_t\}_{t \geq 0}$ be the natural completed filtration of W.

We consider the following stochastic controlled system:

$$dx(t) = b(x(t), u(t))dt + \sigma(x(t), u(t))dW(t),$$
$$x(0) = x_0, \qquad (1)$$

with the cost functional

$$J(u(\cdot)) = \mathbb{E}\left\{\int_0^T f(x(t), u(t))dt + h(x(T))\right\}. \qquad (2)$$

In the above, b, σ, f, h are given functions with appropriate dimensions. (U, d) is a separable metric space.

We define

$$\mathcal{U} = \{u : [0, T] \times \Omega$$
$$\to U \mid u \text{ is } \{\mathcal{F}_t\}_{t \geq 0} - \text{ adapted }\}. \quad (3)$$

The optimal problem is: Minimize $J(u(\cdot))$ over $\mathcal{U}$.

Any $\bar{u} \in \mathcal{U}$ satisfying

$$J(\bar{u}) = \inf_{u \in \mathcal{U}} J(u) \qquad (4)$$

is called an optimal control. The corresponding $\bar{x}$ and $(\bar{x}, \bar{u})$ is called an optimal state process/trajectory and optimal pair, respectively.

In this section, we assume the following standard hypothesis:

Hypothesis 1 *1. The functions $b : \mathbb{R}^n \times U \mapsto \mathbb{R}^n$, $\sigma = (\sigma^1, \cdots, \sigma^m) : \mathbb{R}^n \times U \mapsto \mathbb{R}^{n \times m}$, $f : \mathbb{R}^n \times U \mapsto \mathbb{R}$ and $h : \mathbb{R}^n \mapsto \mathbb{R}$ are measurable functions.*
2. For $\varphi = b, \sigma^j, j = 1, \cdots, m, f$, the functions $x \mapsto \varphi(x, u)$ and $x \mapsto h(x)$ are C^2, denoted φ_x and φ_{xx} (respectively, h_x and h_{xx}), which are also continuous functions of (x, u).
3. There exists a constant $K > 0$ such that

$$|\varphi_x| + |\varphi_{xx}| + |h_x| + |h_{xx}| \leq K,$$

and

$$|\varphi| + |h| \leq K(1 + |x| + |u|).$$

Adjoint Equations

Let us first introduce the following backward stochastic differential equations (BSDEs).

$$dp(t) = -\{b_x(\bar{x}(t), \bar{u}(t))^T p(t) \qquad (5)$$
$$+ \sum_{j=1}^m \sigma_x^j(\bar{x}(t), \bar{u}(t))^T q_j(t)$$
$$- f_x(\bar{x}(t), \bar{u}(t))\}dt + q(t)dW(t),$$
$$p(T) = -h_x(\bar{x}(T)).$$

The solution (p, q) to the above BSDE (first-order BSDE) is called the first-order adjoint process.

$$dP(t) = -\{b_x(\bar{x}(t), \bar{u}(t))^T P(t) + P(t)b_x(\bar{x}(t), \bar{u}(t)) + \sum_{j=1}^m \sigma_x^j(\bar{x}(t), \bar{u}(t))^T P(t)\sigma_x^j(\bar{x}(t), \bar{u}(t))$$

$$+ \sum_{j=1}^m \{\sigma_x^j(\bar{x}(t), \bar{u}(t))^T Q_j(t) + Q_j(t)\sigma_x^j(\bar{x}(t), \bar{u}(t))\}$$

$$+ H_{xx}(\bar{x}(t), \bar{u}(t), p(t), q(t))\}dt + \sum_{j=1}^m Q_j(t)dW^j(t), \qquad (6)$$

$$P(T) = -h_{xx}(\bar{x}(T)),$$

where the Hamiltonian H is defined by

$$H(x, u, p, q) = \langle p, b(x, u) \rangle$$
$$+ \text{tr}[q^T \sigma(x, u)] - f(x, u). \quad (7)$$

The solution (P, Q) to the above BSDE (second-order BSDE) is called the second-order adjoint process.

Stochastic Maximum Principle

Let us now state the stochastic maximum principle.

Theorem 1 *Let* $(\bar{x}, \bar{u})$ *be an optimal pair of problem. Then there exist a unique couple* (p, q) *satisfying* (5) *and a unique couple* (P, Q) *satisfying* (6)*, and the following maximum condition holds:*

$$H(\bar{x}(t), \bar{u}(t), p(t), q(t)) - H(\bar{x}(t), u, p(t), q(t))$$
$$- \frac{1}{2} tr(\{\sigma(\bar{x}(t), \bar{u}(t)) - \sigma(\bar{x}(t), u)\}^T P(t) \{\sigma(\bar{x}(t), \bar{u}(t)) - \sigma(\bar{x}(t), u)\}) \geq 0. \quad (8)$$

SMP in Infinite-Dimensional Space

The problem of finding sufficient conditions for optimality for a stochastic optimal control problem with infinite-dimensional state equation, along the lines of the Pontryagin maximum principle, was already addressed in the early 1980s in the pioneering paper (Bensoussan 1983).

Whereas the Pontryagin maximum principle for infinite-dimensional stochastic control problems is a well-known result as far as the control domain is convex (or the diffusion does not depend on the control; see Bensoussan 1983; Hu and Peng 1990), for the general case (that is when the control domain need not be convex and the diffusion coefficient can contain a control variable), existing results are limited to abstract evolution equations under assumptions that are not satisfied by the large majority of concrete SPDEs.

The technical obstruction is related to the fact that (as it was pointed out in Peng 1990) if the control domain is not convex, the optimal control has to be perturbed by the so-called spike variation. Then if the control enters the diffusion, the irregularity in time of the Brownian trajectories imposes to take into account a second variation process. Thus, the stochastic maximum principle has to involve an adjoint process for the second variation. In the finite-dimensional case, such a process can be characterized as the solution

of a matrix-valued backward stochastic differential equation (BSDE), while in the infinite-dimensional case, the process naturally lives in a non-Hilbertian space of operators and its characterization is much more difficult. Moreover, the applicability of the abstract results to concrete controlled SPDEs is another delicate step due to the specific difficulties that they involve such as the lack of regularity of Nemytskii-type coefficients in L^p spaces.

Concerning results on the infinite-dimensional stochastic Pontryagin maximum principle, as we already mentioned, in Bensoussan (1983) and Hu and Peng (1990), the case of diffusion independent on the control is treated (with the difference that in Hu and Peng (1990) a complete characterization of the adjoint to the first variation as the unique mild solution to a suitable BSDE is achieved).

The paper Tang and Li (1994) is the first one in which the general case is addressed with, in addition, a general class of noises possibly with jumps. The adjoint process of the second variation $(P_t)_{t \in [0,T]}$ is characterized as the solution of a BSDE in the (Hilbertian) space of Hilbert-Schmidt operators. This forces to assume a very strong regularity on the abstract state equation and control functional that prevents application of the results in Tang and Li (1994) to SPDEs.

Then in the papers by Fuhrman et al. (2012, 2013), the state equation is formulated, only in a semiabstract way in order, on one side, to cope

with all the difficulties carried by the concrete nonlinearities and, on the other, to take advantage of the regularizing properties of the leading elliptic operator.

Recently in Lü and Zhang (2012), P_t was characterized as "transposition solution" of a backward stochastic evolution equation in $\mathcal{L}(L^2(\mathcal{O}))$. Coefficients are required to be twice Fréchet differentiable as operators in $L^2(\mathcal{O})$. Finally, even more recently in a couple of preprints (Du and Meng (2012, 2013)), the process P_t is characterized in a similar way as it is in Fuhrman et al. (2012, 2013). Roughly speaking it is characterized as a suitable stochastic bilinear form. As it is the case in Lü and Zhang (2012), in Du and Meng (2012, 2013) as well, the regularity assumptions on the coefficients are too restrictive to apply directly the results in Lü and Zhang (2012), Du and Meng (2012, 2013) to controlled SPDEs.

Stochastic Model Predictive Control

Basil Kouvaritakis and Mark Cannon
Department of Engineering Science, University of Oxford, Oxford, UK

Abstract

Model predictive control (MPC) is a control strategy that has been used successfully in numerous and diverse application areas. The aim of the present entry is to discuss how the basic ideas of MPC can be extended to problems involving random model uncertainty with known probability distribution. We discuss cost indices, constraints, closed-loop properties, and implementation issues.

Keywords

Mean-square stability; Recursive feasibility; Stochastic Lyapunov function

Introduction

Stochastic model predictive control (SMPC) refers to a family of numerical optimization strategies for controlling stochastic systems subject to constraints on the states and inputs of the controlled system. In this approach, future performance is quantified using a cost function evaluated along predicted state and input trajectories. This leads to a stochastic optimal control problem, which is solved numerically to determine an optimal open-loop control sequence or alternatively a sequence of feedback control laws. In MPC, only the first element of this optimal sequence is applied to the controlled system, and the optimal control problem is solved again at the next sampling instant on the basis of updated information on the system state. The numerical nature of the approach makes it applicable to systems with nonlinear dynamics and constraints on states and inputs, while the repeated computation of optimal predicted trajectories introduces feedback to compensate for the effects of uncertainty in the model.

Robust MPC (RMPC) tackles problems with hard state and input constraints, which are to be satisfied for all realizations of model uncertainty. However, RMPC is too conservative in many applications and stochastic MPC (SMPC) provides less conservative solutions by handling a wider class of constraints which are to be satisfied in mean or with a specified probability. This is achieved by taking explicit account of the probability distribution of the stochastic model uncertainty in the optimization of predicted performance. Constraints limit performance and an advantage of MPC is that it allows systems to operate close to constraint boundaries. Stochastic MPC is similarly advantageous when model uncertainty is stochastic with known probability distribution and the constraints are probabilistic in nature.

Applications of SMPC have been reported in diverse fields, including finance and portfolio management, risk management, sustainable development policy assessment, chemical and process industries, electricity generation and distribution, building climate control, andtelecommunications network traffic control. This entry aims to summarize the theoretical framework underlying SMPC algorithms.

Stochastic MPC

Consider a system with discrete time model

$$x^+ = f(x, u, w) \qquad (1)$$

$$z = g(x, u, v) \qquad (2)$$

where $x \in \mathbb{R}^{n_x}$ and $u \in \mathbb{R}^{n_u}$ are the system state and control input and x^+ is the successor state (i.e., if x_i is the state at time i, then $x^+ = x_{i+1}$ is the state at time $i + 1$). Inputs $w \in \mathbb{R}^{n_w}$ and $v \in \mathbb{R}^{n_v}$ are exogenous disturbances with unknown current and future values but known probability distributions, and $z \in \mathbb{R}^{n_z}$ is a vector of output variables that are subject to constraints.

The optimal control problem that is solved online at each time step in SMPC is defined in terms of a performance index $J_N(x, \hat{\mathbf{u}}, \hat{\mathbf{w}})$ evaluated over a future horizon of N time steps. Typically in SMPC $J_N(x, \hat{\mathbf{u}}, \hat{\mathbf{w}})$ is a quadratic function of the following form (in which $\|x\|_Q^2 = x^T Q x$)

$$J_N(x, \hat{\mathbf{u}}, \hat{\mathbf{w}}) = \sum_{i=0}^{N-1} (\|\hat{x}_i\|_Q^2 + \|\hat{u}_i\|_R^2) + V_f(\hat{x}_N) \qquad (3)$$

for positive definite matrices Q and R, and a terminal cost $V_f(x)$ defined as discussed in section "Stability and Convergence." Here $\hat{\mathbf{u}} := \{\hat{u}_0, \ldots, \hat{u}_{N-1}\}$ is a postulated sequence of control inputs and $\hat{\mathbf{x}}(x, \hat{\mathbf{u}}, \hat{\mathbf{w}}) := \{\hat{x}_0, \ldots, \hat{x}_N\}$ is the corresponding sequence of states such that $\hat{x}_i$ is the solution of (1) at time i with initial state $\hat{x}_0 = x$, for a given sequence of disturbance inputs $\hat{\mathbf{w}} := \{\hat{w}_0, \ldots, \hat{w}_{N-1}\}$. Since $\hat{\mathbf{w}}$ is a random sequence, $J_N(x, \hat{\mathbf{u}}, \hat{\mathbf{w}})$ is a random variable, and the optimal control problem is therefore formulated as the minimization of a cost $V_N(x, \hat{\mathbf{u}})$ derived from $J_N(x, \hat{\mathbf{u}}, \hat{\mathbf{w}})$ under specific assumptions on $\hat{\mathbf{w}}$. Common definitions of $V_N(x, \hat{\mathbf{u}})$ are as follows.

S

(a) Expected value cost:

$$V_N(x, \hat{\mathbf{u}}) := \mathbb{E}_x(J(x, \hat{\mathbf{u}}, \hat{\mathbf{w}}))$$

where $\mathbb{E}_x(\cdot)$ denotes the conditional expectation of a random variable $(\cdot)$ given the model state x.

(b) Worst-case cost, assuming $\hat{w}_i \in \mathcal{W}$ for all i with probability 1, for some compact set $\mathcal{W} \subset \mathbb{R}^{n_w}$:

$$V_N(x, \hat{\mathbf{u}}) := \max_{\hat{\mathbf{w}} \in \mathcal{W}^N} J(x, \hat{\mathbf{u}}, \hat{\mathbf{w}}).$$

(c) Nominal cost, assuming $\hat{w}_i$ is equal to some nominal value, e.g., if $\hat{w}_i = 0$ for all i, then

$$V_N(x, \hat{\mathbf{u}}) := J(x, \hat{\mathbf{u}}, \mathbf{0}),$$

where $\mathbf{0} = \{0, \ldots, 0\}$.

The minimization of $V_N(x, \hat{\mathbf{u}})$ is performed subject to constraints on the sequence of outputs $\hat{z}_i := g(\hat{x}_i, \hat{u}_i, \hat{v}_i)$, $i \geq 0$. These constraints may be formulated in various ways, summarized as follows, where for simplicity we assume $n_z = 1$.

(A) Expected value constraints: for all i,

$$\mathbb{E}_x(\hat{z}_i) \leq 1.$$

(B) Probabilistic constraints pointwise in time:

$$\Pr_x(\hat{z}_i \leq 1) \geq p,$$

for all i and for a given probability p.

(C) Probabilistic constraints over a future horizon:

$$\Pr_x(\hat{z}_i \leq 1, \ i = 0, 1, \ldots, N) \geq p$$

for a given probability p.

In (B) and (C), $\Pr_x(\mathcal{A})$ represents the conditional probability of an event $\mathcal{A}$ that depends on the sequence $\hat{\mathbf{x}}(x, \hat{\mathbf{u}}, \hat{\mathbf{w}})$, given that the initial model state is $\hat{x}_0 = x$; for example the probability $\Pr_x(\hat{z}_i \leq 1)$ depends on the distribution of $\{\hat{w}_0, \ldots, \hat{w}_{i-1}, \hat{v}_i\}$.

The important special case of state constraints can also be handled by (A)–(C) through appropriate choice of the function $g(x, u, v)$. For example the constraint $\Pr_x(h(x) \leq 1) \geq p$, for a given function $h : \mathbb{R}^n \to \mathbb{R}$, can be expressed in the form (B) with $z = g(x, u, v) := h(f(x, u, w))$ and $v := w$ in (2).

In common with other receding horizon control strategies, SMPC is implemented via the following algorithm. At each discrete time step:

 (i) Minimize the cost index $V_N(x, \hat{\mathbf{u}})$ over $\hat{\mathbf{u}}$ subject to the constraints on $\hat{z}_i$, $i \geq 0$, given the current system state x.

(ii) Apply the control input $u = \hat{u}_0^*(x)$ to the system, where $\hat{\mathbf{u}}^*(x) = \{\hat{u}_0^*(x), \ldots, \hat{u}_{N-1}^*(x)\}$ is the minimizing sequence given x.

If the system dynamics (1) are unstable, then performing the optimization in step (i) directly over future control sequences can result in a small set of feasible states x. To avoid this difficulty the elements of the control sequence $\hat{\mathbf{u}}$ are usually expressed in the form $\hat{u}_i = u_T(\hat{x}_i) + s_i$, where $u_T(x)$ is a locally stabilizing feedback law, and $\{s_0, \ldots, s_{N-1}\}$ are optimization variables in step (i).

Constraints and Recursive Feasibility

The constraints in (B) and (C) include hard constraints ($p = 1$) as a special case, but in general the conditions (A)–(C) represent soft constraints that are not required to hold for all realizations of model uncertainty. However, these constraints can only be satisfied if the state belongs to a subset of state space, and the requirement (common in MPC) that the optimization in step (i) of the SMPC algorithm should remain feasible if it is initially feasible therefore implies additional constraints. For example, the condition $\Pr_x(\hat{z}_0 \leq 1) \geq p$ can be satisfied only if x belongs to the set for which there exists $\hat{u}_0$ such that $\Pr_x(g(x, \hat{u}_0, \hat{v}_0) \leq 1) \geq p$. Hence, soft constraints implicitly impose hard constraints on the model state.

SMPC algorithms typically handle the conditions relating to feasibility of constraint sets in

one of two ways. Either the SMPC optimization is allowed to become infeasible (often with penalties on constraint violations included in the cost index), or conditions ensuring robust feasibility of the SMPC optimization at all future times are imposed as extra constraints in the SMPC optimization.

The first of these approaches has been used in the context of constraints (C) imposed over a horizon, for which conditions ensuring future feasibility are generally harder to characterize in terms of algebraic conditions on the model state than (A) or (B). A disadvantage of this approach is that the closed-loop system may not satisfy the required soft constraints, even if these constraints are feasible when applied to system trajectories predicted at initial time.

The second approach treats conditions for feasibility as hard constraints and hence requires a guarantee of recursive feasibility, namely, that the SMPC optimization must remain feasible for the closed-loop system if it is feasible initially. This can be achieved by requiring, similarly to RMPC, that the conditions for feasibility of the SMPC optimization problem should be satisfied for all realizations of the sequence $\hat{\mathbf{w}}$. For example, for given $\hat{x}_0 = x$, there exists $\hat{\mathbf{u}}$ satisfying that the conditions of (B) if

$$\Pr_{\hat{x}_i}(g(\hat{x}_i, \hat{u}_i, \hat{v}_i) \leq 1) \geq p, \, i = 0, 1, \dots \quad (4a)$$

$$\hat{x}_i \in X \, \forall \{\hat{w}_0, \dots, \hat{w}_{i-1}\} \in \mathcal{W}^i, \, i = 1, 2, \dots \quad (4b)$$

where X is the set

$$X = \{x : \exists u \text{ such that } \Pr_x(g(x, u, v) \leq 1) \geq p\}.$$

Furthermore, an SMPC optimization that includes the constraints of (4) must remain feasible at subsequent times (since (4) ensures the existence of $\hat{\mathbf{u}}^+$ such that each element of $\hat{\mathbf{x}}(f(x, \hat{u}_0, \hat{w}_0), \hat{\mathbf{u}}^+, \hat{\mathbf{w}}^+)$ lies in X for all $\hat{w}_0 \in \mathcal{W}$ and all $\hat{\mathbf{w}}^+ \in \mathcal{W}^N$).

Satisfaction of (4) at each time step i on the infinite horizon $i \geq N$ can be ensured through a finite number of constraints by introducing constraints on the N-step-ahead state $\hat{x}_N$. This approach uses a fixed feedback law, $u_T(x)$, to define a postulated input sequence after the initial N-step horizon via $\hat{u}_i = u_T(\hat{x}_i)$ for all $i \geq N$. The constraints of (4) are necessarily satisfied for all $i \geq N$ if a constraint

$$\hat{x}_N \in X_T$$

is imposed, where X_T is robustly positively invariant with probability 1 under $u_T(x)$, i.e.

$$f(x, u_T(x), w) \in X_T, \, \forall x \in X_T, \, \forall w \in \mathcal{W}, \quad (5)$$

and furthermore the constraint $\Pr_x(z \leq 1) \geq p$ is satisfied at each point in X_T under $u_T(x)$, i.e.,

$$\Pr_x(g(x, u_T(x), v) \leq 1) \geq p, \, \forall x \in X_T.$$

Although the recursively feasible constraints (4) account robustly for the future realizations of the unknown parameter w in (1), the key difference between SMPC and RMPC is that the conditions in (4) depend on the probability distribution of the parameter v in (2). It also follows from the necessity of hard constraints for feasibility that the distribution of w must in general have finite support in order that feasibility can be guaranteed recursively. On the other hand the support of v in the definition of z may be unbounded (an important exception being the case of state constraints in which $v = w$).

Stability and Convergence

This section outlines the stability properties of SMPC strategies based on cost indices (a)–(c) of section "Stochastic MPC" and related variants. We use $V_N^*(x) = V_N(x, \hat{\mathbf{u}}^*(x))$ to denote the optimal value of the SMPC cost index, and X_T denotes a subset of state space satisfying the robust invariance condition (5). We also denote the solution at time i of the system (1) with initial state $x_0 = x$ and under a given feedback control law $u = \kappa(x)$ and disturbance sequence $\mathbf{w} = \{w_0, w_1, \dots\}$ as $x_i(x, \kappa, \mathbf{w})$.

The expected value cost index in (a) results in mean-square stability of the closed-loop system provided the terminal term $V_f(x)$ in (3) satisfies

$$\mathbb{E}_x V_f(f(x, u_T(x), w) \leq V_f(x) - \|x\|_Q^2$$
$$- \|u_T(x)\|_R^2$$

for all x in the terminal set X_T. The optimal cost is then a stochastic Lyapunov function satisfying

$$\mathbb{E}_x V_N^*(f(x, \hat{u}_0^*(x), w)) \leq V_N^*(x) - \|x\|_Q^2$$
$$- \|\hat{u}_0^*(x)\|_R^2.$$

For positive definite Q this implies the closed-loop system under the SMPC law is mean-square stable, so that $x_i(x, \hat{u}_0^*, \mathbf{w}) \to 0$ as $i \to \infty$ with probability 1 for any feasible initial condition x. For the case of systems (1) subject to additive disturbances, the modified cost

$$V_N(x, \hat{\mathbf{u}}) := \mathbb{E}_x \left[\sum_{i=0}^{N-1} (\|\hat{x}_i\|_Q^2 + \|\hat{u}_i\|_R^2 - l_{ss}) + V_f(\hat{x}_N) \right]$$

where $l_{ss} := \lim_{i \to \infty} \mathbb{E}_x(\|x_i(x, u_T, \mathbf{w})\|_Q^2 + \|u_i\|_R^2)$ under $u_i = u_T(x_i)$ results in the asymptotic bound

$$\lim_{n \to \infty} \frac{1}{n} \sum_{i=0}^{n-1} \mathbb{E}_x(\|x_i(x, \hat{u}_0^*, \mathbf{w})\|_Q^2 + \|u_i\|_R^2) \leq l_{ss}$$

along the closed-loop trajectories of (1) under the SMPC law $u_i = \hat{u}_0^*(x_i)$, for any feasible initial condition x.

For the worst-case cost (b), if $V_f(x)$ is designed as a control Lyapunov function for (1), with

$$V_f(f(x, u_T(x), w) \leq V_f(x) - \|x\|_Q^2 - \|u_T(x)\|_R^2$$

for all $w \in \mathcal{W}$ and all $x \in X_T$, then $V_N^*(x)$ is a Lyapunov function satisfying

$$V_N^*(f(x, \hat{u}_0^*(x), w) \leq V_N^*(x) - \|x\|_Q^2 - \|\hat{u}_0^*(x)\|_R^2$$

for all $w \in \mathcal{W}$, implying $x = 0$ is an asymptotically stable equilibrium of (1) under the SMPC law $u = \hat{u}_0^*(x)$. Clearly the system model (1) cannot be subject to unknown additive disturbances in this case. However, for the case in which the system (1) is subject to additive disturbances, a variant of this approach uses a modified cost which is equal to zero inside some set of states, leading to asymptotic stability of this set rather than an equilibrium point. Also in the context of additive disturbances, an alternative approach uses an $\mathcal{H}_\infty$-type cost,

$$V_N(x, \hat{\mathbf{u}}) := \max_{\hat{\mathbf{w}} \in \mathcal{W}^N} \left[\sum_{i=0}^{N-1} (\|\hat{x}_i\|_Q^2 + \|\hat{u}_i\|_R^2 - \gamma^2 \|\hat{w}_i\|^2) + V_f(\hat{x}_N) \right]$$

for which the closed-loop trajectories of (1) under the associated SMPC law $u_i = \hat{u}_0^*(x_i)$ satisfy

$$\sum_{i=0}^{\infty} (\|x_i(x, \hat{u}_0^*, \mathbf{w})\|_Q^2 + \|u_i\|_R^2) \leq \gamma^2$$
$$\sum_{i=0}^{\infty} \|w_i\|^2 + V_N^*(x_0)$$

provided $V_f(f(x, u_T(x), w)) \leq V_f(x) - (\|x\|_Q^2 + \|u_T(x)\|_R^2 - \gamma^2 \|w\|^2)$ for all $w \in \mathcal{W}$ and $x \in X_T$.

Algorithms employing the nominal cost (c) typically rely on the existence of a feedback law $u_T(x)$ such that the system (1) satisfies, in the absence of constraints and under $u_i = u_T(x_i)$, an input-to-state stability (ISS) condition of the form

$$\sum_{i=0}^{\infty} (\|x_i(x, u_T, \mathbf{w})\|_Q^2 + \|u_i\|_R^2) \leq \gamma^2 \sum_{i=0}^{\infty} \|w_i\|^2 + \beta \tag{6}$$

for some γ and $\beta > 0$. If $V_f(x)$ satisfies

$$V_f(f(x, u_T(x), 0)) \leq V_f(x) - (\|x\|_Q^2 + \|u_T(x)\|_R^2)$$

for all $x \in X_T$, then the closed-loop system under SMPC with the nominal cost (c) satisfies an ISS condition with the same gain γ as the unconstrained case (6) but a different constant β.

Implementation Issues

In general stochastic MPC algorithms require more computation than their robust counterparts because of the need to determine the probability distributions of future states. An important exception is the case of linear dynamics and purely additive disturbances, for which the model (1)–(2) becomes

$$x^+ = Ax + Bu + w \qquad (7)$$

$$z = Cx + Du + v \qquad (8)$$

where A, B, C, D are known matrices. In this case the expected value constraints (A) and probabilistic constraints (B), as well as hard constraints that ensure future feasibility of the SMPC optimization in each case, can be invoked nonconservatively through tightened constraints on the expectations of future states. Furthermore, the required degree of tightening can be computed off-line using numerical integration of probability distributions or using random sampling techniques, and the online computational load is similar to MPC with no model uncertainty.

The case in which the matrices A, B, C, D in the model (7)–(8) depend on unknown stochastic parameters is more difficult because the predicted states then involve products of random variables. An effective approach to this problem uses a sequence of sets (known as a tube) to recursively bound the sequence of predicted states via one step-ahead set inclusion conditions. By using polytopic bounding sets that are defined as the intersection of a fixed number of half-spaces, the complexity of these tubes can be controlled by the designer, albeit at the expense of conservative inclusion conditions. Furthermore, an application of Farkas' Lemma allows these sets

to be computed online through linear conditions on optimization variables.

Random sampling techniques developed for general stochastic programming problems provide effective means of handling the soft constraints arising in SMPC. These techniques use finite sets of discrete samples to represent the probability distributions of model states and parameters. Furthermore bounds are available on the number of samples that are needed in order to meet specified confidence levels on the satisfaction of constraints. Probabilistic and expected value constraints can be imposed using random sampling, and this approach has also been applied to the case of probabilistic constraints over a horizon (C) through a scenario-based optimization approach.

Summary and Future Directions

This entry describes how the ideas of MPC and RMPC can be extended to the case of stochastic model uncertainty. Crucial in this development is the assumption that the uncertainty has bounded support, which allows the assertion of recursive feasibility of the SMPC optimization problem. For simplicity of presentation we have considered the case of full-state feedback. However, stochastic MPC can also be applied to the output feedback case using a state estimator if the probability distributions of measurement and estimation noise are known.

An area of future development is optimization over sequences of feedback policies. Although an observer at initial time cannot know the future realizations of random uncertainty, information on $\hat{x}_i$ will be available to the controller i-steps ahead, and, as mentioned in section "Stochastic MPC" in the context of feasible initial condition sets, $\hat{u}_i$ must therefore depend on $\hat{x}_i$. In general the optimal control decision is of the form $\hat{u}_i = \mu_i(\hat{x}_i)$ where $\mu_i(\cdot)$ is a feedback policy. This implies optimization over arbitrary feedback policies, which is generally considered to be intractable since the required online computation grows exponentially with the

horizon N. However, approximate approaches to this problem have been suggested which optimize over restricted classes of feedback laws, and further developments in this respect are expected in the future.

Recommended Reading

A historical perspective on SMPC is provided by Åström and Wittenmark (1973), Charnes and Cooper (1963), and Schwarm and Nikolaou (1999). A treatment of constraints stated in terms of expected values can be found, for example, in Primbs and Sung (2009). Probabilistic constraints and the conditions for recursive feasibility can be found in Kouvaritakis et al. (2010) for the additive case, whereas the general case of multiplicative and additive uncertainty is described in Evans et al. (2012), which uses random sampling techniques. Random sampling techniques were developed for random convex programming (Calafiore and Campi 2005) and were used in a scenario-based approach to predictive control in Calafiore and Fagiano (2013). An output feedback SMPC strategy incorporating state estimation is described in Cannon et al. (2012).

The use of the expectation of a quadratic cost and associated mean-square stability results are discussed in Lee and Cooley (1998). Robust stability results for MPC based on worst-case costs are given by Lee and Yu (1997) and Mayne et al. (2005). Input-to-state stability of MPC based on a nominal cost is discussed in Marruedo et al. (2002).

Descriptions of SMPC based on closed-loop optimization can be found in Lee and Yu (1997) and Stoorvogel et al. (2007). These algorithms are computationally intensive and approximate solutions can be found by restricting the class of closed-loop predictions as discussed, for example, in van Hessem and Bosgra (2002) and Primbs and Sung (2009).

Stock Trading via Feedback Control

B. Ross Barmish[1] and James A. Primbs[2]
[1]University of Wisconsin, Madison, WI, USA
[2]University of Texas at Dallas, Richardson, TX, USA

Abstract

This article covers stock trading from a feedback control point of view. To this end, the mechanics and practical considerations associated with the use of feedback-based algorithms are explained for both real-world trading and scenarios involving numerical simulation.

Keywords and Phrases

Feedback Control; Finance; Model-Free; Stock Trading

Introduction

Stock trading involves the purchase and sale of *shares* of ownership in public companies by an individual or entity such as a pension fund, mutual fund, hedge fund, or endowment. These shares are typically traded in markets, such as the New York Stock Exchange and the NASDAQ, with the trader's goal generally being to increase wealth. The words *feedback control* in the title of this article broadly refer to the use of information such as prices, profits and losses which becomes available to the trader over time and is used to make purchase and sales decisions according to some set of rules. That is, the size of the stock position being held varies with time. The mapping from information to the investment level is called the *feedback law* and is typically described with a closed-loop configuration and

classical algorithms which come from the body of research called control theory; e.g., see Astrom and Murray (2008).

For simplicity, in this article, we restrict attention to trading a single stock while noting that the concepts described herein are readily modified to address the multi-stock case, i.e., a *portfolio*. To our knowledge, the basic idea of viewing portfolios in a control-theoretic setting goes back to Merton (1969) where optimal control concepts are explicitly used; see also Samuelson (1969) where a less general formulation is considered. Whereas the theoretical foundations in their work rely on idealized assumptions such as "frictionless markets" and "continuous trading," the main objective in this article is to describe the practical considerations and complexities which arise in real-world stock trading via feedback control and associated simulations. That is, the exposition to follow includes no significant idealizing assumptions and emphasizes implementation issues and constraints which are encountered by the practitioner; i.e., the purpose of this article is to describe trading mechanics in a feedback context. Hence, when we define a trading strategy in the sequel, we include no significant discussion of performance metrics related to risk and return; the reader is referred to the book by Luenberger (1998) for coverage of these topics.

Feedback Versus Open-Loop Control

We first elaborate on the definitions above by pointing out the distinction between trading a stock via feedback control and its alternative, "open-loop control." This is done via simple examples: Suppose an investor buys $1,000 of stock at time $t = 0$ with the a priori plan to make no changes in this position until some prespecified future time $t = T$. Then, this *buy-and-hold* trading strategy falls within the realm of open-loop control. If instead this same investor adds $1,000 to the position every month, then this type of *dollar-cost averaging* strategy would still fall into the open-loop category. That is, in both scenarios, no information is being used to modify the stock position over time. Finally, suppose this same investor makes a $1,000 purchase only at the end

of those months over which the account value has decreased. Then this type of *buy-low* investor is now using a simple feedback control strategy because gain-loss information is being used to modify the stock position over time. The ability of feedback to cope with the uncertainty of future price movements is an important advantage of its use in trading.

Closed-Loop Feedback Configuration

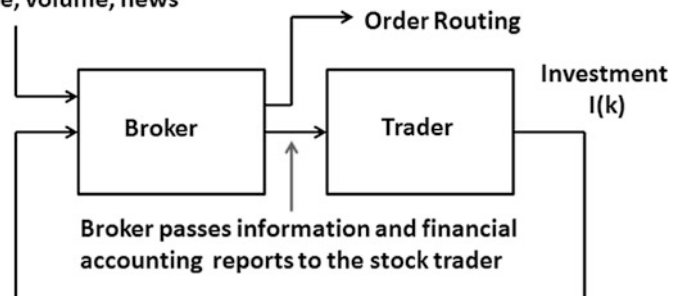
To describe stock trading via feedback control in a more formal manner, the first step involves the creation of a closed-loop feedback configuration involving the trader and the broker; see Fig. 1. In the figure, the feedback controller resides inside the block labeled "trader." There is a wide diversity of possible algorithms which the trader can use to modify the investment level over time. In some cases, a fixed model for future stock prices is central to the trading algorithm. Oftentimes, no stock price model is used at all, and trading signals are generated based on "price patterns." This falls under the umbrella "technical analysis" in its purest form; e.g., see the books by Kirkpatrick and Dahlquist (2007) and Lo and Hasanhodzic (2010) for further details. In any event, regardless of the trading method used, the time-varying control signal is the investment level $I(t)$.

Discrete Time and Short Selling

Since this article aims to describe real-world stock-trading mechanics as opposed to theoretical results, we work in discrete time. That is, the initial investment at time $t = 0$ is denoted by $I_0 = I(0)$, and assuming trade updates can be performed every Δt units of time, $I(t)$ is replaced by $I(k) \doteq I(k\Delta t)$. We also allow for the possibility that $I(k) < 0$. In this case, the trader is called a *short seller* and the following is meant: Shares valued at $I(k)$ are borrowed from the broker and immediately sold in the market in the hope that the price will decline. If such a decline occurs, the short seller can "cover" the position and realize a profit by buying back the stock and returning the borrowed shares to the broker. Alternatively, if the stock price increases, the short seller can continue to hold the position with a "paper loss" or buy back the borrowed stock at a loss. For the more classical case when $I(k) > 0$, the trade is said to be *long*. Finally, to conclude this section, analogous to what was done for the investment, we use the notation $p(k), g(k)$, and $V(k)$ to represent the stock price, trading gains or losses, and account value at time $t = k\Delta t$.

First Ingredient: Price Data

A trading system, be it a simulation or real-money implementation, involves sequential price data $p(k)$. This can be obtained either in real time or can be historical stock market data. As far as historical data is concerned, there are various recognized sources that provide end-of-day "closing prices," adjusted for splits and dividends. These can be downloaded for free from Yahoo! Finance. Another possibility, available from the Wharton

Stock Trading via Feedback Control, Fig. 1 Feedback loop involving trader and broker


Research Data Services for a subscription fee, is the comprehensive database of historical prices at time scales from monthly to tick by tick.

It is also possible to conduct stock-trading simulations using synthetic data. For example, one of the most common ways that synthetic prices are generated is via a geometric Brownian motion process. That is, a process *drift* μ and a *volatility* $\sigma > 0$, say on an annualized basis, are provided to the simulator, and prices are generated sequentially in time via a recursion such as the Euler scheme with iterates

$$p(k+1) = \left(1 + \mu \Delta t + \sigma \epsilon(k) \sqrt{\Delta t}\right) p(k)$$

where Δt is measured in years and $\epsilon(k)$ is a zero-mean normally distributed random variable with unit standard deviation. A code used for simulation of stock trading should also include a check that $p(k) \geq 0$. The reader is referred to the textbook by Oksendal (1998) for a detailed description of this celebrated stochastic price model.

Second Ingredient: The Feedback Law

The second ingredient for trading is the previously mentioned mapping taking the information available to the trader to the amount invested $I(k)$. This feedback law is the "heart" of the controller and allows it to adapt to uncertain and changing market conditions. Perhaps the simplest example of a stock-trading *feedback law* is obtained using a classical linear time-invariant controller. In this case, the trader modulates the level of investment $I(k)$ in proportion to the cumulative gains or losses from trading according to the formula

$$I(k) = I_0 + Kg(k).$$

This is an example of technical analysis with no stock price model being used; see Fig. 2.

Using the feedback law above, the trader initially invests $I(0) = I_0$ in the stock and then begins to monitor the cumulative gain or loss $g(k)$ associated with this investment. One begins

with states $g(0) = 0$ and $I(0)$ and subsequently changes $I(k)$ if the position begins to either make or lose money depending on the movement of the stock. The constant of proportionality K above, the so-called feedback gain, is used to scale the investment level. When I_0 and K are positive, $I(k)$ is initially positive and the trade is long. Alternatively, when I_0 and K are negative, $I(k)$ is initially negative; hence, the trader is a short seller. This type of classical linear feedback is an example of a strategy which falls within the well-known class of "trend followers."

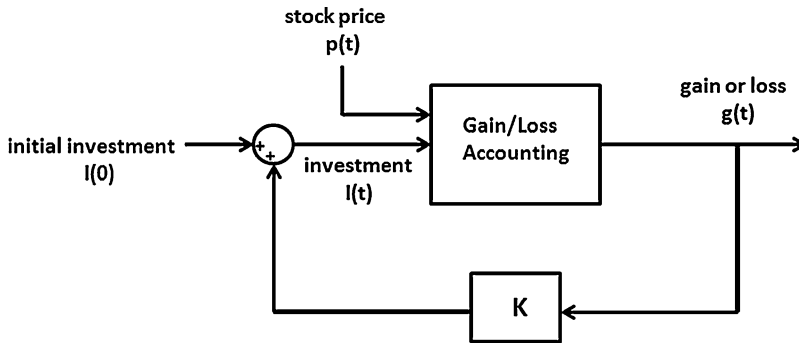
As a second example, we consider a long trade with $I_0, K > 0$ and investor who wishes to limit the trade to some level $I_{\max} > I_0$. In this case, the feedback loop includes a nonlinear saturation block, see Fig. 3, and the update equation for investment is

$$I(k) = \min\{I_0 + Kg(k), I_{\max}\}.$$

A short-trade version of the above can similarly be defined and there are also variations of this scheme, involving the notion of "reset," which assures that excessive time is not spent in the saturation regime when the stock price is falling after a long period of increase or decrease.

In the formula above and in the sequel, for simplicity, we allow $I(k)$ to represent a fractional number of shares. In practice, this type of fractional holding is only allowed in some restricted situations such as reinvestment of dividends or dollar allocations to buy shares of a mutual fund. However, in cases where a significant number of shares are being bought or sold, the use of fractional shares is a good approximation which can be used for all practical purposes. Finally, to conclude this section, we mention a subtlety which is easily overlooked in a simulation: If the intention of the trader is to be "long," then $I(k) < 0$ should be ruled out by including the condition $I(k) = \max\{I(k), 0\}$ as part of the control logic.

Order-Filling Mechanics

At time $t = k\Delta t$, the trader specifies the desired investment update to the broker who is responsible for providing a "fill" via interaction


Stock Trading via Feedback Control, Fig. 2 Stock trading via linear feedback
Stock Trading via Feedback Control, Fig. 3 Feedback loop with saturation

with the stock exchange. The way this step is carried out depends on a number of factors: If the stock being purchased is not heavily traded, there may be "liquidity" issues which manifest themselves as "bid-ask spread." In general, there will always exist an ask price and a bid price for any stock in the market. To see how a liquidity issue can arise, imagine a trader who wishes to purchase 100 shares at the ask price of $100 per share. If there are only 75 shares available at $100, the trader will need to pay more for the second portion of the purchase. For example, if there are 500 shares available with an ask price of $102 and transaction costs charged by the broker are 5 cents per share, the following will occur: The trader will obtain 100 shares with two "partial fills" and end up with an average acquisition cost of $100.55. This type of bid-ask gap scenario may arise for a large trader such as a hedge fund. For example, if millions of shares are being purchased at time $t = k\Delta t$, the price

of the final shares acquired may be significantly higher than the initial shares.

In the case when a stock trades with large daily volume, if large "market movers" such as hedge funds are not transacting, it can often be assumed in simulations that the trader is a *price taker*. That is, one assumes bid-ask spread is zero and trading is said to be "highly liquid." The final point to mention is that there are different order types which can be specified by the trader. The three most common *order types* are called *market*, *limit*, and *stop*.

The bottom line on order filling is as follows: When stock trading is carried out or simulated, all of the complications above can be handled via appropriate interpretation of the stock price $p(k)$ at time $t = k\Delta t$. This is accomplished as follows: When a trade is executed, be it with multiple transactions or as a special order type, we take $p(k)$ to be the average weighted price. For example, to illustrate for a long trade involving

two transactions, suppose a trader arrives at investment level $I(k)$ via two trades: the first is investment $I_a(k)$ to purchase shares at price $p_a(k)$ and the second is an investment $I_b(k)$ to purchase shares at price $p_b(k)$. Then, the average cost to acquire these shares is readily calculated to be

$$p(k) = \frac{p_a(k)p_b(k)}{p_a(k)I_b(k) + p_b(k)I_a(k)}\Delta I(k).$$

where $\Delta I(k)$ is the amount of the stock transaction at time $t = k\Delta t$. This quantity is given by

$$\Delta I(k) = I(k) - (1 + \rho(k-1))I(k-1)$$

where

$$\rho(k-1) \doteq \frac{p(k) - p(k-1)}{p(k-1)}$$

is the *percentage change* in the stock price from $k-1$ to k. Subsequently, transactions at later times $t > k\Delta t$ can be carried out as if all shares were acquired at price $p(k)$.

When this multiple-transaction issue arises in real trading, it may not be possible to predict in advance what price $p(k)$ will result. For example, in the 100-share scenario above, the outcome depended on the bid-ask queue. Notice that this did not present a problem as far as gain-loss accounting is concerned; i.e., the average price per share \$100.55 was readily calculated. However, when it comes to simulation, a model for "share acquisition" would need to be assumed. For example, for the case of geometric Brownian motion described earlier, a common model is that the trader is a price taker and that liquidity is sufficiently high so that an order involving investment $\Delta I(k)$ is filled at the sample-path price $p(k)$; i.e., no averaging over multiple transactions is required.

Gain-Loss Accounting

A broker generally provides frequent updates on gains and losses $g(k)$ attributable to stock price changes. That is,

$$g(k+1) = g(k) + \rho(k)I(k) - T(k)$$

where $T(k)$ is the so-called transaction costs, most of which consist of the broker's commission. These costs are charged for each trade and are much lower nowadays versus decades ago. For example, using a discount broker, one can easily obtain commission rates of less than \$5 per trade, even when a large number of shares are being transacted. Modulo the transaction costs, the equation above simply states that the change in the cumulative gain or loss $\Delta g(k)$ over a time increment Δt is equal to the investment $I(k)$ multiplied by the return on the stock $\Delta p(k)/p(k)$.

Interest Accumulation and Margin Charges

In many brokerage accounts, it is possible to borrow funds or shares from the broker to purchase or short sell a stock. This is referred to as trading on *margin* and the broker will charge an interest rate on the borrowed funds known as the *margin rate*. While in practice there is a limit on how much money can be borrowed, it can be quite large; e.g., hedge funds can easily obtain access to many multiples of their account value. Another possibility is that the trader is not fully invested and the account contains "idle cash" on which interest, paid by the broker, accrues.

To cover both the interest and margin accrual, we work with the *account cash*, surplus or shortfall, to determine whether interest is accrued or margin charges need to be paid. For a long trade with $I(k) > 0$ for the period Δt, we work with the *broker interest rate*, often called the risk-free return, $r_f > 0$, or the *broker margin rate m* to obtain the *interest accrual*

$$A(k) = r_f \max\{V(k) - I(k), 0\}$$
$$+ m \min\{V(k) - I(k), 0\}.$$

For the case of a short trade with $I(k) < 0$, the formula above will only hold for traders with very large accounts who have sufficient leverage with the broker so as to be allowed to capitalize on the proceeds of a short sale. For the typical

small- to medium-size trading account, the short-sale proceeds are generally "held aside" and the account is "marked to market" on a daily basis. As a result, the $A(k)$ equation above needs to be revised to account for "cash in reserve" and turns out to provide smaller interest rate accruals to the trader.

Finally, the broker's report generally includes the entire value of the account $V(k)$. This number is made up of the stock positions, either idle or borrowed cash and "dividends" $D(k)$ which may be paid periodically to the trader by the company whose shares are being held. Thus, the broker performs the calculation

$$V(k + 1) = V(0) + g(k) + A(k) + D(k)$$

and a trader can typically see these updates in real time.

Collateral Requirements and Margin Calls

When formulating the simulation model for trading, it is important to take account of the fact that the size of the trader's investment $I(k)$ is limited by the collateral requirements of the broker. For example, when a long stock position falls dramatically, a trader on margin may find that $I(k)$ exceeds the account value $V(k)$ by too large an amount to meet the broker's collateral requirements. In this case, new transactions are "stopped" and a so-called in guates results; i.e., to avoid forced liquidation of positions to bring the account back into compliance, the trader must deposit new assets or cash into the account within a short prespecified time period. In simulations, for a brokerage account with total market value $V(k)$, a constraint of the sort

$$|I(k)| \leq \gamma V(k)$$

can be imposed with $\gamma = 2$ being rather typical.

Simulation Example

We provide a simulation example illustrating the use of control in stock trading and its ability to adapt to the inherent uncertainty in stock price

movements. Figure 4 shows the daily closing prices from January 1, 2008 to June 1, 2012 of Google (GOOG), traded on the NASDAQ stock exchange. The figure also includes the 50-day simple moving average $p_{\mathrm{av}}(k)$ which will be used with a control law whose investment level depends on sign changes in $p(k) - p_{\mathrm{av}}(k)$; see Brock et al. (1992) where moving average crossing strategies are studied. There is no trading during the first 50 days while the moving average is being initialized. Subsequently, the trading begins at the first instant $k = k^*$ when the moving average has been crossed. For $k \geq k^*$, the control law for the investment level is given by

$$I(k) = I_0 \mathrm{sign}\{p(k) - p_{\mathrm{av}}(k)\}$$

where $I_0 = \$20,000$ is used in the simulation. To make the example more interesting, we assume initial account value $V(0) = \$10,000$. Hence, the issue of margin is immediately in play. In the simulation, we use risk-free rate $r_f = 0.015$ corresponding to 1.5 % per annum and a margin rate $m = 0.03$ corresponding to 3 % per annum. It is assumed that interest may be obtained on the proceeds of short sales at the risk-free rate. Google does not pay a dividend, so no adjustment of closing prices is required. A transaction cost of $3 per trade is charged. This charge occurs every day of trading because the position is adjusted daily to target $I(k) = \pm\$20,000$. We assume the broker imposes a collateral constraint of $|I(k)| \leq 2V(k)$ to limit $I(k)$ when sufficient funds are not available. Furthermore, we assume that it is possible to hold a fractional number of shares and that a "market-on-close" order each day is filled at the closing price. Finally, Fig. 4 also shows the evolution of the account value $V(k)$ over time.

Summary and Future Directions

This article concentrated entirely on trading mechanics and simulation using strategies based on control-theoretic considerations. In a future version of the encyclopedia, it would be desirable to include a "companion" article which covers the topic of *performance metrics*. That is, once trading or simulation is complete, it is natural to
Stock Trading via Feedback Control, Fig. 4 Feedback trading of Google

ask whether the algorithm used was successful or not. To this end, there is a large body of literature covering measures for risk and return which are important for performance strategy evaluation purposes. One highlight of this literature is the paper by Artzner et al. (1999) on coherent risk measures, a topic pursued in current research.

Recommended Reading

In addition to the basic references cited in the previous sections, there is a growing body of literature on stock trading and financial markets with a control-theoretic flavor. In contrast to this article, the focal point in this literature is largely performance-related issues rather than the "nuts and bolts" of stock-trading mechanics which are described here. For the uninitiated reader, one starting reference for an overview of the literature would be the tutorial paper by Barmish et al. (2013). To provide a capsule summary, it is convenient to subdivide the literature into two categories: The first category, called *model-based* approaches, involves an underlying parameterized model structure which may or may not be completely specified. The second category of papers, called *model-free* approaches, falls under the previously mentioned umbrella of technical analysis. That is, the stock price is viewed as an external input with no predictive model for its evolution. In addition, no parameter estimation is involved and feedback trade signals are generated based on some observed "patterns" of prices or trading gains. Thus, this line of research highlights the ability of feedback to cope with the uncertainty of an unmodelled price process.

Nash Equilibrium

Abstract

This chapter introduces strategic form games, which provide a framework for the analysis of strategic interactions in multi-agent environments. We present the main solution concept in strategic form games, *Nash equilibrium*, and provide tools for its systematic study. We present fundamental results for existence and uniqueness of Nash equilibria and discuss their efficiency properties. We conclude with current research directions in this area.

Keywords

Efficiency; Existence; Nash equilibrium; Strategic form games; Uniqueness

Introduction

Many problems in communication, decision, and technological networks as well as in social and economic situations depend on human choices,

which are made in anticipation of the behavior of the others in the system. Examples include how to map your drive over a road network, how to use the communication medium, and how to choose strategies for resource use and more conventional economic, financial, and social decisions such as which products to buy, which technologies to invest in, or who to trust. The defining feature of all of these interactions is the dependence of an agent's objective (payoff, utility, or survival) on others' actions. Game theory focuses on formal analysis of such strategic interactions. Here, we will review strategic form games, which focus on static game-theoretic interactions and present the relevant solution concept.

Strategic Form Games

A *strategic form* game is a model for a static game in which all players act simultaneously without knowledge of other players' actions.

Definition 1 (Strategic Form Game) A strategic form game is a triplet
$\langle \mathcal{I}, (S_i)_{i \in \mathcal{I}}, (u_i)_{i \in \mathcal{I}} \rangle$ where:
1. $\mathcal{I}$ is a finite set of players, $\mathcal{I} = \{1, \ldots, I\}$.
2. S_i is a nonempty set of available actions for player i.
3. $u_i : S \to \mathbb{R}$ is the utility (payoff) function of player i where $S = \prod_{i \in \mathcal{I}} S_i$.

We will use the terms *action* and *(pure) strategy* interchangeably. (We will later use the term "mixed strategy" to refer to randomizations over actions.) We denote by $s_i \in S_i$ an action for player i, and by $s_{-i} = [s_j]_{j \neq i}$ a vector of actions for all players *except i*. We refer to the tuple $(s_i, s_{-i}) \in S$ as an *action (strategy) profile* or *outcome*. We also denote by $S_{-i} = \prod_{j \neq i} S_j$ the set of actions (strategies) of all players except i. Our convention throughout will be that each player i is interested in action profiles that "maximize" his utility function u_i.

The next two examples illustrate strategic form games with finite and infinite strategy sets.

Example 1 (Finite Strategy Sets) We consider a two-player game with finite strategy sets. Such a two-player game can be represented in matrix form, where the rows correspond to the actions of player 1 and columns represent the actions of player 2. The cell indexed by row x and column y contains a pair (a, b), where a is the payoff to player 1 and b is the payoff to player 2, i.e., $a = u_1(x, y)$ and $b = u_2(x, y)$. This class of games is sometimes referred to as *bimatrix games*. For example, consider the following game of "Matching Pennies."

|	HEADS	TAILS
HEADS	$-1, 1$	$1, -1$
TAILS	$1, -1$	$-1, 1$

Matching Pennies

This game represents "pure conflict" in the sense that one player's utility is the negative of the utility of the other player, i.e., the sum of the utilities for both players at each outcome is "zero." This class of games is referred to as *zero-sum games* (or *constant-sum games*) and has been studied extensively in the game theory literature (Basar and Olsder 1995).

Example 2 (Infinite Strategy Sets) We next present a game with infinite strategy sets. We consider a simple network game where two players send data or information flows over a communication network represented by a single link. Each player i derives a value for sending s_i units of flow over the link given by

$$v_i(s_i) = \begin{cases} a_i s_i - \frac{s_i^2}{2} & \text{if } s_i \leq a_i, \\ \frac{a_i^2}{2} & \text{if } s_i \geq a_i, \end{cases}$$

where $a_i \in [0, 1]$ is a player-specific scalar. Each player also incurs a per-flow delay or latency cost, due to congestion on the link, represented by the function $l(s) = s$, where s is the total flow on the link, i.e., $s = s_1 + s_2$ (see Fig. 1). The resulting interactions can be represented by the strategic form game $\langle \mathcal{I}, (S_i), (u_i) \rangle$, which consists of:
1. A set of two players, $\mathcal{I} = 1, 2$
2. A strategy set $S_i = [0, 1]$ for each player i, where $s_i \in S_i$ represents the amount of flow player i sends over the link
3. A utility function u_i for each player i given by value derived from sending s_i units of flow minus the total latency cost, i.e.,
Strategic Form Games and Nash Equilibrium, Fig. 1
A network game with two players

$$u_i(s_1, s_2) = v_i(s_i) - s_i l(s_1 + s_2).$$

Nash Equilibrium

We next introduce the fundamental solution concept for strategic form games, *Nash equilibrium*. A Nash equilibrium captures a steady state of the play in a strategic form game such that each player acts optimally given their "correct" conjectures about the behavior of the other players.

Definition 2 (Nash Equilibrium) A *(pure strategy) Nash equilibrium* of a strategic form game $\langle \mathcal{I}, (S_i), (u_i)_{i \in \mathcal{I}} \rangle$ is a strategy profile $s^* \in S$ such that for all $i \in \mathcal{I}$, we have

$$u_i(s_i^*, s_{-i}^*) \geq u_i(s_i, s_{-i}^*) \qquad \text{for all } s_i \in S_i.$$

Hence, a Nash equilibrium is a strategy profile s^* such that no player i can profit by unilaterally deviating from his strategy s_i^*, assuming every other player j follows his strategy s_j^*. The definition of a Nash equilibrium can be restated in terms of best-response correspondences.

Definition 3 (Nash Equilibrium – Restated) Let $\langle \mathcal{I}, (S_i), (u_i)_{i \in \mathcal{I}} \rangle$ be a strategic form game. For any $s_{-i} \in S_{-i}$, consider the best-response correspondence of player i, $B_i(s_{-i})$, given by

$$B_i(s_{-i}) = \{s_i \in S_i \mid u_i(s_i, s_{-i}) \geq u_i(s_i', s_{-i})$$
$$\text{for all } s_i' \in S_i\}.$$

We say that an action profile s^* is a *Nash equilibrium* if

$$s_i^* \in B_i(s_{-i}^*) \qquad \text{for all } i \in \mathcal{I}.$$

Thus, if we define the best-response correspondence $B(s) = [B_i(s_{-i})]_{i \in \mathcal{I}}$, the set of Nash equilibria is given by the set of fixed points of $B(s)$. Below, we give two examples of games with pure strategy Nash equilibria.

Example 3 (Battle of the Sexes) Consider a two-player game with the following payoff structure:

	BALLET	SOCCER
BALLET	2, 1	0, 0
SOCCER	0, 0	1, 2

Battle of the Sexes

This game, referred to as the Battle of the Sexes game, represents a scenario in which the two players wish to coordinate their actions but have different preferences over their actions. This game has two pure strategy Nash equilibria, i.e., the strategy profiles (BALLET, BALLET) and (SOCCER, SOCCER).

Example 4 Recall the network game given in Example 2. To simplify the computations, let us assume without loss of generality that $a_1 \geq a_2 \geq \frac{a_1}{3}$. It can be seen that the best-response functions (single-valued in this case) of the players are given by

$$B_i(s_{-i}) = \max\left\{0, \frac{a_i - s_{-i}}{3}\right\} \qquad \text{for } i = 1, 2.$$

The unique pure strategy Nash equilibrium of this game is the fixed point of these functions given by

$$(s_1^*, s_2^*) = \left(\frac{3a_1 - a_2}{8}, \frac{3a_2 - a_1}{8}\right).$$

Mixed Strategy Nash Equilibrium

Consider the two-player "penalty kick" game between a penalty taker and a goalkeeper that has the same payoff structure as the matching pennies:

	LEFT	RIGHT
LEFT	1, −1	−1, 1
RIGHT	−1, 1	1, −1

Penalty kick game

This game does not have a pure strategy Nash equilibrium. It can be verified that if the penalty taker (column player) commits to a pure strategy, e.g., chooses LEFT, then the best response of the goalkeeper (row player) would be to choose the same side leading to a payoff of -1 for the penalty taker. In fact, the penalty taker would be better off following a strategy which randomizes between LEFT and RIGHT, ensuring that the goalkeeper cannot perfectly match his action. This is the idea of "randomized" or mixed strategies which we will discuss next.

We first introduce some notation. Let Σ_i denote the set of probability measures over the pure strategy (action) set S_i. We use $\sigma_i \in \Sigma_i$ to denote the *mixed strategy* of player i. When S_i is a finite set, a mixed strategy is a finite-dimensional probability vector, i.e., a vector whose elements denote the probability with which a particular action will be played. For example, if S_i has two elements, the set of mixed strategies Σ_i is the one-dimensional probability simplex, i.e., $\Sigma_i = \{(x_1, x_2) \mid x_i \geq 0, x_1 + x_2 = 1\}$. We use $\sigma \in \Sigma = \prod_{i \in \mathcal{I}} \Sigma_i$ to denote a *mixed strategy profile*. Note that this implicitly assumes that players randomize independently. We similarly denote $\sigma_{-i} \in \Sigma_{-i} = \prod_{j \neq i} \Sigma_j$.

Following von Neumann-Morgenstern expected utility theory, we extend the payoff functions u_i from S to Σ by

$$u_i(\sigma) = \int_S u_i(s) d\sigma(s),$$

i.e., the payoff of a mixed strategy σ is given by the expected value of pure strategy payoffs under the distribution σ.

We are now ready to define the mixed strategy Nash equilibrium.

Definition 4 (Mixed Strategy Nash Equilibrium) A mixed strategy profile σ^* is a *mixed strategy Nash equilibrium* if for each player i,

$$u_i(\sigma_i^*, \sigma_{-i}^*) \geq u_i(\sigma_i, \sigma_{-i}^*) \qquad \text{for all } \sigma_i \in \Sigma_i.$$

Note that since $u_i(\sigma_i, \sigma_{-i}^*) = \int_{S_i} u_i(s_i, \sigma_{-i}^*) d\sigma_i(s_i)$, it is sufficient to check only *pure* strategy

"deviations" when determining whether a given profile is a Nash equilibrium. This leads to the following characterization of a mixed strategy Nash equilibrium.

Proposition 1 *A mixed strategy profile σ^* is a mixed strategy Nash equilibrium if and only if for each player i,*

$$u_i(\sigma_i^*, \sigma_{-i}^*) \geq u_i(s_i, \sigma_{-i}^*) \qquad \text{for all } s_i \in S_i.$$

We also have the following useful characterization of a mixed strategy Nash equilibrium in finite strategy set games.

Proposition 2 *Let $G = \langle \mathcal{I}, (S_i)_{i \in \mathcal{I}}, (u_i)_{i \in \mathcal{I}} \rangle$ be a strategic form game with finite strategy sets. Then, $\sigma^* \in \Sigma$ is a Nash equilibrium if and only if for each player $i \in \mathcal{I}$, every pure strategy in the support of σ_i^* is a best response to σ_{-i}^*.*

Proof Let σ^* be a mixed strategy Nash equilibrium, and let $E_i^* = u_i(\sigma_i^*, \sigma_{-i}^*)$ denote the expected utility for player i. By Proposition 1, we have

$$E_i^* \geq u_i(s_i, \sigma_{-i}^*) \qquad \text{for all } s_i \in S_i.$$

We first show that $E_i^* = u_i(s_i, \sigma_{-i}^*)$ for all s_i in the support of σ_i^* (combined with the preceding relation, this proves one implication). Assume to arrive at a contradiction that this is not the case, i.e., there exists an action s_i' in the support of σ_i^* such that $u_i(s_i', \sigma_{-i}^*) < E_i^*$. Since $u_i(s_i, \sigma_{-i}^*) \leq E_i^*$ for all $s_i \in S_i$, this implies that

$$\sum_{s_i \in S_i} \sigma_i^*(s_i) u_i(s_i, \sigma_{-i}^*) < E_i^*,$$

which is a contradiction. The proof of the other implication is similar and is therefore omitted.

It follows from this characterization that every action in the support of any player's equilibrium mixed strategy yields the same payoff. This characterization extends to games with infinite strategy sets: $\sigma^* \in \Sigma$ is a Nash equilibrium if and only if for each player $i \in \mathcal{I}$, given σ_{-i}^*, no action

in S_i yields a payoff that exceeds his equilibrium payoff, and the set of actions that yields a payoff less than his equilibrium payoff has σ_i^*-measure zero.

Example 5 Let us return to the Battle of the Sexes game.

	BALLET	SOCCER
BALLET	2, 1	0, 0
SOCCER	0, 0	1, 2

Battle of the Sexes

Recall that this game has 2 pure strategy Nash equilibria. Using the characterization result in Proposition 2, we show that it has a *unique* mixed strategy Nash equilibrium (which is not a pure strategy Nash equilibrium). First, by using Proposition 2 (and inspecting the payoffs), it can be seen that there are no Nash equilibria where only one of the players randomizes over its actions. Now, assume instead that player 1 chooses the action BALLET with probability $p \in (0, 1)$ and SOCCER with probability $1 - p$ and that player 2 chooses BALLET with probability $q \in (0, 1)$ and SOCCER with probability $1 - q$. Using Proposition 2 on player 1's payoffs, we have the following relation:

$$2 \times q + 0 \times (1 - q) = 0 \times q + 1 \times (1 - q).$$

Similarly, we have

$$1 \times p + 0 \times (1 - p) = 0 \times p + 2 \times (1 - p).$$

We conclude that the only possible mixed strategy Nash equilibrium is given by $q = \frac{1}{3}$ and $p = \frac{2}{3}$.

Existence of Nash Equilibrium

The first question that one contemplates in analyzing a strategic form game is whether it has a pure or mixed strategy Nash equilibrium. While it may be possible to explicitly construct a Nash equilibrium (using either computational means or characterization results), this may be a tedious task in the case of both large finite strategy set games or infinite strategy set games with complicated utility functions. One is therefore often interested in establishing existence of an equilibrium, using conditions on the utility functions and constraint sets, before trying to understand its properties. In the sequel, we present results on existence of an equilibrium for games with finite and infinite strategy sets. The proofs of such existence results typically use fixed point arguments on the best-response correspondences of the players. They are omitted here and can be found in graduate-level game theory text books (see Fudenberg and Tirole 1991 and Myerson 1991).

Finite Strategy Set Games

We have seen that while the matching pennies game (and the penalty kick game with the same payoff structure) does not have a pure strategy Nash equilibrium, it has a mixed strategy Nash equilibrium. The next theorem, states that this existence result extends to all finite strategy set games.

Theorem 1 (Nash) *Every strategic form game with finite strategy sets has a mixed strategy Nash equilibrium.*

Infinite Strategy Set Games

A stronger result on existence of a pure strategy Nash equilibrium can be established in infinite strategy set games under some topological conditions on the utility functions and constraint sets (see Debreu 1952, Fan 1952, and Glicksberg 1952).

Theorem 2 (Debreu, Fan, Glicksberg) *Consider a strategic form game $\langle \mathcal{I}, (S_i)_{i \in \mathcal{I}}, (u_i)_{i \in \mathcal{I}} \rangle$ with infinite strategy sets such that for each $i \in \mathcal{I}$:*

1. S_i is convex and compact.
2. $u_i(s_i, s_{-i})$ is continuous in s_{-i}.
3. $u_i(s_i, s_{-i})$ is continuous and quasiconcave in s_i. (Let X be a convex set. A function $f : X \to \mathbb{R}$ is quasiconcave if every upper level set of the function, i.e., $\{x \in X \mid f(x) \geq \alpha\}$ for every scalar α, is a convex set (see Bertsekas et al. 2003).)

The game has a pure strategy Nash equilibrium.

Note that Theorem 1 is a special case of this result. For games with finite strategy sets, mixed strategy sets are simplices and hence are convex and compact, and utilities are linear in (mixed) strategies; hence, they are concave functions of (mixed) strategies (and continuous functions of mixed strategy profiles).

The next example shows that quasiconcavity cannot be dispensed with in the previous existence result.

Example 6 Consider the game where two players pick a location $s_1, s_2 \in \mathbb{R}^2$ on the circle. The payoffs are

$$u_1(s_1, s_2) = -u_2(s_1, s_2) = d(s_1, s_2),$$

where $d(s_1, s_2)$ denotes the Euclidean distance between s_1 and $s_2 \in \mathbb{R}^2$. It can be verified that this game does not have a pure strategy Nash equilibrium. However, the strategy profile where both players mix uniformly on the circle is a mixed strategy Nash equilibrium.

Without quasiconcavity, one can establish the following existence result (see Glicksberg 1952).

Theorem 3 (Glicksberg) *Consider a strategic form game $\langle \mathcal{I}, (S_i)_{i \in \mathcal{I}}, (u_i)_{i \in \mathcal{I}} \rangle$, where the S_i are nonempty compact metric spaces and the $u_i : S \to \mathbb{R}$ are continuous functions. The game has a mixed strategy Nash equilibrium.*

Uniqueness of Nash Equilibrium

Another important question that arises in the analysis of strategic form games is whether the Nash equilibrium is unique. This is important for the predictive power of Nash equilibrium since with multiple equilibria, the outcome of the game cannot be uniquely pinned down. The following result by Rosen provides sufficient conditions for uniqueness of an equilibrium in games with infinite strategy sets (see Rosen 1965). (Except for games that are strictly dominant solvable, there are no general uniqueness results for finite strategic form games.)

We first introduce some notation to state this result. Given a scalar-valued function $f : \mathbb{R}^n \to \mathbb{R}$, we use the notation $\nabla f(x)$ to denote the gradient vector of f at point x, i.e.,

$$\nabla f(x) = \left[\frac{\partial f(x)}{\partial x_1}, \dots, \frac{\partial f(x)}{\partial x_n} \right]^T.$$

Given a scalar-valued function $F : \prod_{i=1}^{I} \mathbb{R}^{m_i} \to \mathbb{R}$, we use the notation $\nabla_i F(x)$ to denote the gradient vector of F with respect to x_i at point x, i.e.,

$$\nabla_i F(x) = \left[\frac{\partial F(x)}{\partial x_i^1}, \dots, \frac{\partial F(x)}{\partial x_i^{m_i}} \right]^T.$$

We use the notation $\nabla F(x)$ to denote

$$\nabla F(x) = [\nabla_1 F_1(x), \dots, \nabla_I F_I(x)]^T. \quad (1)$$

We assume that the strategy set S_i of each player i is given by

$$S_i = \{ x_i \in \mathbb{R}^{m_i} \mid h_i(x_i) \geq 0 \}, \quad (2)$$

where $h_i : \mathbb{R}^{m_i} \mapsto \mathbb{R}$ is a concave function. (Since h_i is concave, it follows that the set S_i is a convex set.) The next definition introduces the key condition used in establishing the uniqueness of a pure strategy Nash equilibrium.

Definition 5 We say that the utility functions $(u_1, \dots, u_I)$ are **diagonally strictly concave** for $x \in S$, if for every $x^*, \bar{x} \in S$, we have

$$(\bar{x} - x^*)^T \nabla u(x^*) + (x^* - \bar{x})^T \nabla u(\bar{x}) > 0.$$

We can now state the result on uniqueness of pure strategy Nash equilibrium in strategic form games.

Theorem 4 (Rosen) *Consider a strategic form game $\langle \mathcal{I}, (S_i), (u_i) \rangle$. For all $i \in \mathcal{I}$, assume that the strategy sets S_i are given by Eq. (2), where h_i is a concave function, and there exists some $\tilde{x}_i \in \mathbb{R}^{m_i}$ such that $h_i(\tilde{x}_i) > 0$. Assume also that the utility functions $(u_1, \dots, u_I)$ are diagonally strictly concave for $x \in S$. Then, the game has a unique pure strategy Nash equilibrium.*

S

We next provide a tractable sufficient condition for the utility functions to be diagonally strictly concave. Let $U(x)$ denote the Jacobian of $\nabla u(x)$ [see Eq. (1)]. Specifically, if the x_i are all 1-dimensional, then $U(x)$ is given by

$$U(x) = \begin{pmatrix} \frac{\partial^2 u_1(x)}{\partial x_1^2} & \frac{\partial^2 u_1(x)}{\partial x_1 \partial x_2} & \cdots \\ \frac{\partial^2 u_2(x)}{\partial x_2 \partial x_1} & \ddots & \\ \vdots & & \end{pmatrix}.$$

Proposition 3 (Rosen) *For all $i \in \mathcal{I}$, assume that the strategy sets S_i are given by Eq. (2), where h_i is a concave function. Assume that the symmetric matrix $(U(x) + U^T(x))$ is negative definite for all $x \in S$, i.e., for all $x \in S$, we have*

$$y^T (U(x) + U^T(x))y < 0, \qquad \forall \, y \neq 0.$$

Then, the payoff functions $(u_1, \ldots, u_I)$ are diagonally strictly concave for $x \in S$.

Rosen's sufficient conditions for uniqueness are quite strong. Recent work has extended such uniqueness results to hold under weaker conditions using differential topology tools. The main idea is to provide sufficient conditions so that the indices of all stationary points can be shown to be positive, which from a generalization of the Poincare-Hopf theorem (Simsek et al. 2007, 2008) implies that there exists a unique equilibrium (see Simsek et al. 2005 for applications of this methodology to several network games).

Efficiency of Nash Equilibria

Because the Nash equilibrium corresponds to the fixed point of the best-response correspondences of the players, there is no presumption that it is efficient or maximizes any well-defined weighted sum of utility functions of the players. This fact is clearly illustrated by the well-known Prisoner's Dilemma game. For some $a > 0, b > 0$, and $c > 0$ with $a > b$, the payoff matrix is given by:

	DON'T CONFESS	CONFESS
DON'T CONFESS	a, a	$b-c, a+c$
CONFESS	$a+c, b-c$	b, b

Prisoner's Dilemma

This game, generally used for capturing the dilemma of cooperation among selfish agents, has a unique (pure strategy) Nash equilibrium. (In fact each player has a dominant strategy, see Fudenberg and Tirole 1991, which is (CONFESS, CONFESS)). This clearly illustrates two aspects of the inefficiencies that arise in Nash equilibria. First, the unique Nash equilibrium is Pareto inferior meaning that if both players cooperated and chose DON'T CONFESS, they would both obtain the higher payoff of a. Second, the extent of inefficiency can be arbitrarily large based on the values of a and b. We can capture this by the *efficiency loss* (or *Price of Anarchy* as known in the literature) defined as

$$\text{Efficiency Loss} = \inf_{\text{parameters}} \frac{\sum_i u_i(\text{equilibrium})}{\sum_i u_i(\text{social optimum})},$$

where the social optimum is the strategy profile that maximizes the sum of utility functions. In the preceding example, this is clearly

$$\inf_{a,b} \frac{b}{a} = 0,$$

showing that efficiency loss can be arbitrarily large. In problems that have more structure, the efficiency loss can be bounded away from zero. A well-known example is by Pigou, which showed that in a network routing game where the congestion penalty can be described by linear latency functions (see Example 2), the efficiency loss is 3/4 (Pigou 1920). Roughgarden and Tardos in an important contribution (Roughgarden and Tardos 2000) showed that this is a lower bound for such routing games over all possible network topologies.

Summary and Future Directions

This article has provided an introduction to the basics of strategic form games. After defining the concept of Nash equilibrium, which is the basis of much of recent game theory, we have

presented fundamental results on its existence and uniqueness. We also briefly discussed issues of efficiency of Nash equilibria.

Though game theory is a mature field, there are still several important areas for inquiry. The first is a more systematic analysis and categorization of classes of games by their equilibrium and efficiency properties. Recent work by Candogan et al. (2010, 2011, 2013) provides tools for systematically analyzing equivalence classes of games that may be useful for such an investigation. The second area that is very much active concerns computational issues, which we have not considered here. Recent literature showed that computation of Nash equilibria in finite strategy set games is potentially hard and focused on developing algorithms for computing approximate Nash equilibria (see Daskalakis et al. 2006 and Lipton et al. 2003). Ongoing research in this area focuses on infinite strategy set games and exploits special structure to develop algorithms for computing (exact and approximate) Nash equilibria (Parrilo 2006; Stein et al. 2008). A third area is to develop a better application of tools of strategic form games and understand the resulting efficiency losses in networks and large-scale systems. Work in this area uses game-theoretic models to investigate resource allocation, pricing, and investment problems in networks (Johari and Tsitsiklis 2004; Acemoglu and Ozdaglar 2007; Acemoglu et al. 2009; Njoroge et al. 2013). A fourth area of research is to develop and apply alternative solution concepts for strategic form games. While some of the research in game theory has focused on subsets of Nash Equilibria (see Fudenberg and Tirole 1991), from a computational point of view, the set of correlated equilibria, which is a superset of the set of Nash Equilibria, is also attractive since it can be represented as the optimal solution set of a linear program. Correlated equilibrium can be implemented using a correlation scheme (a trusted party) or cryptographic tools as shown in Izmalkov et al. (2007). Recent work investigates alternative solution concepts for symmetric games intermediate between Nash and correlated equilibria (Stein et al. 2013), which can be implemented using specific correlation schemes.

Stream of Variations Analysis

Jianjun Shi
Georgia Institute of Technology, Atlanta, GA, USA

Abstract

Stream of variation (SoV) theory is a unified, model-based method for modeling, analyzing, and controlling variation in multistage manufacturing systems. A SoV model represents variation and its propagation in a multistage system using the recursive structure of state space models; such models can be derived from physical knowledge and/or estimated empirically using system operational data. Immediately, the SoV model enables integrated design and optimization for product and process tolerancing, allocation of distributed sensors in production lines, and evaluation of multistage system designs. With the help of these functions, the SoV method fulfills the objectives of system monitoring, diagnosis, and control and, ultimately, reduces a system's variation during its operation. The SoV method can be further extended to model the interactions among product quality and tooling reliability, known as the quality and reliability chain effects, which is the crucial element in carrying out quality-ensured maintenance, as well as system reliability evaluation and optimization. The SoV theory has been successfully implemented in assembly, machining, and semiconductor manufacturing processes. More research and development are needed to extend the SoV theory to manufacturing systems with complex configurations.

Keywords

Data fusion; Engineering-driven statistics; Multistage manufacturing system; Quality improvement; Variation reduction

Introduction

A multistage system refers to a system consisting of multiple units, stations, or operations to finish a final product or a service. Multistage systems are ubiquitous in modern manufacturing processes and service systems. In most cases, the final product or service quality of a multistage system is determined by complex interactions among multiple stages – the quality characteristics of one stage are not only influenced by the local variations at that stage but also by the variations propagated from upstream stages. Multistage systems present significant challenges for quality engineering research and system improvement.

The stream of variation (SoV) theory has been developed to understand and represent the complex production stream and data stream involved in the modeling and analysis of variation and its propagation in a multistage manufacturing system (Fig. 1).
Stream of Variations Analysis, Fig. 1 Variation propagation in a multistage manufacturing process (MMP) and notations in SoV modeling (Reproduced from Shi 2006)

Stream of Variation Model

The foundation of the SoV theory is a mathematical model that links the key product quality characteristics with key process control characteristics (e.g., fixture error, machine error, etc.) in a multistage system. This model has a state space representation that describes the deviation and its propagation in an N-stage process (as shown in Fig. 1) and takes the form of

$$\mathbf{x}_k = \mathbf{A}_{k-1}\mathbf{x}_{k-1} + \mathbf{B}_k\mathbf{u}_k + \mathbf{w}_k, \quad k = 1, 2, \ldots, N, \tag{1}$$

$$\mathbf{y}_k = \mathbf{C}_k\mathbf{x}_k + \mathbf{v}_k, \quad \{k\} \subset \{1, 2, \ldots, N\}, \tag{2}$$

where k is the stage index, $\mathbf{x}_k$ is the state vector representing the key quality characteristics of the product (or intermediate work piece) after stage k, $\mathbf{u}_k$ is the control vector representing the tooling deviations (e.g., no fault occurs if all tooling deviations are within their tolerances; fault occurs when excessive tooling deviations are beyond their tolerances; active adjustments of tooling deviations can be done to achieve error compensation objectives) at stage k, and $\mathbf{y}_k$ is the measurement vector representing product quality measurements at stage k. Vectors $\mathbf{w}_k$ and $\mathbf{v}_k$ represent modeling error and sensing error, respectively. The coefficient matrices $\mathbf{A}_k$, $\mathbf{B}_k$, and $\mathbf{C}_k$ are determined by product and process design information: $\mathbf{A}_k$ represents the impact of the deviation transition from stage $k-1$ to stage k, $\mathbf{B}_k$ represents the impact of the local tooling deviation on the product quality at stage k, and $\mathbf{C}_k$ is the measurement matrix, which can be

obtained from the defined quality features of the product at stage k.

If we repeat the modeling efforts for each stage from $k = 1$ to N, we will get the deviation and its propagation throughout the multistage manufacturing systems. By taking variances on both sides of (1) and (2) and by assuming independence among certain variables, we will obtain the variation and its propagation model for the multistage manufacturing system.

The SoV models (1) and (2) can be obtained from product and process design information and/or from the system operational data. In Shi (2006), two basic modeling methods, a physics-driven method and a data-driven method, were investigated. In the physics-driven modeling, the kinematic relationships between key control characteristics (KCC) and key product characteristics (KPC) are identified through a detailed physical analysis of the product and manufacturing process. A set of carefully defined coordinate systems are defined to represent the whole system, including the quality features in the part coordinates, part orientation to fixture/machine coordinates, and tooling to fixture/machine coordinates. Based on these coordinate systems, SoV models (1) and (2) are obtained using the state space model framework. In the data-driven modeling approach, system operational data are measured for those selected KPC and KCC variables. System identification and estimation methods are adopted to construct the SoV model. In some cases, data mining and clustering techniques are used to identify inherent relationships of the system in pre-processing. The SoV model may have different formulations, such as

the state space model, input-output model, and piecewise linear regression tree model. In most cases, engineering-driven statistical analysis is commonly used in the data analysis and modeling efforts.

With models (1) and (2), variation reduction can be achieved in both design and manufacturing phases by using mathematical optimization to make optimal decisions. However, significant challenges exist in both the model development for specific processes and model utilization to realize the benefits of the analytical capability of this model. These challenges are addressed in the SoV methodological research (Shi 2006). In more detail, the SoV methodology addresses the following important questions for variation reduction in a multistage manufacturing process.

SoV-Enabled Monitoring and Diagnosis

In multistage manufacturing systems, it is challenging to systematically find the root causes of a severe variability in terms of isolating both the manufacturing station and the underlying cause in that station. During continuous production, excessive product variation may occur at any stage of a multistage manufacturing system due to worn tooling, tooling breakage, and/or abnormal incoming part variation. The SoV theory presents systematic approaches for root cause identification. In this approach, a new concept of "statistical methods driven by engineering models" is proposed to integrate the product and process design knowledge with the on-line statistics. By solving the difference equation of models (1) and (2) and with some mathematical simplifications, the SoV model can be transformed into an input-output format as

$$\mathbf{y} = \boldsymbol{\Gamma} \cdot \mathbf{u} + \boldsymbol{\varepsilon}, \tag{3}$$

where $\mathbf{y}$ is an $n \times 1$ vector of product quality measurements, $\boldsymbol{\Gamma}$ is an $n \times p$ constant system matrix determined by product/process designs, $\mathbf{u}$ is a $p \times 1$ random vector representing the process faults, and $\boldsymbol{\varepsilon}$ is an $n \times 1$ random vector representing measurement noises, un-modeled faults, and high-order nonlinear terms. During production, the product quality features ($\mathbf{y}$) are measured, and the data are used to conduct statistical analysis based on the model (1) to identify root causes. Two basic methods are developed for root cause diagnosis: (i) variation pattern matching: In this method, all potential variation patterns can be obtained from the matrix $\boldsymbol{\Gamma}$ resulting from the off-line system design. During the system operation, observed variation patterns can be obtained from the covariance matrix of $\mathbf{y}$. A pattern matching can be performed to identify the root causes. (ii) estimation-based diagnosis: With the SoV model and availability of on-line measurement of quality feature ($\mathbf{y}$), the deviation value of $\mathbf{u}$ can be estimated on-line. A hypothesis testing of $\mathbf{u}$ and its variance reveals the significant changes that occurred to $\mathbf{u}$, corresponding to the root causes of the system. Various estimators and their performances are evaluated in the diagnosis study (Chapter 11 of Shi 2006).

SoV-Enabled Sensor Allocation and Diagnosability

The issue of diagnosability refers to the problem of whether the product measurements contain sufficient information for the diagnosis of critical process faults, i.e., if root causes of process faults can be diagnosed. The diagnosability analysis is investigated based on model (3) that links potential process faults ($\mathbf{u}$) and product quality measurements ($\mathbf{y}$). In the SoV theory, a set of criteria is developed to evaluate the *mean* diagnosability and *variance* diagnosability for a system. Similar to observability in control theory, diagnosability is determined by the $\mathbf{A}_k$, $\mathbf{B}_k$, and $\mathbf{C}_k$ matrices ($k = 1, \ldots, N$) in the SoV models (1) and (2) (or the $\boldsymbol{\Gamma}$ matrix in model (3)). In some cases, only a subset of variables (vs. specific root cause variables) can be identified as potential root causes of the process faults, which are referred to as minimum diagnosable classes.

One emphasis in the SoV-enabled diagnosability study is to promote the concept of the "process-oriented measurement" strategy. In

current industrial practice, most of the existing measurement strategies focus on the product coherence inspection (i.e., product-oriented measurements), which is effective for detecting product imperfection, but may not be effective to identify the root causes of product quality failures. The SoV theory proposes a "process-oriented measurement" concept with a distributed sensing strategy. In this strategy, selected key control characteristics, as well as selected key product characteristics, will be measured in the selected stages for both detecting product defects and identifying their root causes.

SoV-Enabled Design and Optimization

Variation analysis and design evaluations are conducted in the product and process design stage to identify critical components, features, and manufacturing operations. With the SoV model defined in (3) and certain assumptions, we can represent the KPC-to-KCC relationship as

$$\tilde{\boldsymbol{\Sigma}}_y = \sum_{k=1}^{N} \boldsymbol{\Gamma}_k \boldsymbol{\Sigma}_{u_k} \boldsymbol{\Gamma}_k^T, \tag{4}$$

where $\tilde{\boldsymbol{\Sigma}}_y$ is the variance-covariance matrix of product quality features resulting from the variance-covariance matrix $(\boldsymbol{\Sigma}_{u_k})$ of tooling errors. Based on (3) and (4), the following four tasks can be performed: (i) tolerance analysis by allocating the tooling tolerance $(\mathbf{u}_k)$ and then predicting the final product tolerance $(\mathbf{y}_N)$; (ii) tolerance synthesis by fixing the final product tolerance $(\mathbf{y}_N)$ and then assigning the tolerance for individual tooling components $(\mathbf{u}_k)$ with certain cost objectives minimized; (iii) sensitivity study by identifying the critical tooling components $(\mathbf{u}_k)$ that have significant impacts on the final production variation through evaluation of the defined sensitivity indices; and (iv) process planning by optimizing parameters in $\mathbf{A}_k$ and $\mathbf{B}_k$ matrices to minimize the final product variation.

One unique feature of SoV-enabled design and optimization is to provide a unified method for simultaneous optimization of product and process tooling tolerance, as well as process planning. This is because the SoV models (1) and (2) represent the product quality features ($\mathbf{x}_k$ and $\mathbf{y}_k$), tooling features ($\mathbf{u}_k$), and the process planning formation ($\mathbf{A}_k$ and $\mathbf{B}_k$) within one mathematical model. As a result, a math-based optimization is feasible to achieve the best quality through process-oriented tolerance synthesis for product and process, as well as optimized process planning.

SoV-Enabled Process Control and Quality Compensation

The SoV model provides the opportunity to apply active control for dimensional variation reduction in a multistage manufacturing system. The basic idea is to implement a system-level control strategy during production to minimize the end-of-line product variance, which is propagated from upstream manufacturing stages. An optimal control scheme was devised to use the state space structure of the SoV model by treating the control as a stochastic discrete-time predictive control problem. The optimization index for determining the optimal control action is formulated as

$$J_k^* = \min_{\mathbf{u}_k} J_k = \min_{\mathbf{u}_k} E\left[\hat{\mathbf{y}}_{N|k}^T \mathbf{Q}_N \hat{\mathbf{y}}_{N|k} + \mathbf{u}_k^T \mathbf{R}_k \mathbf{u}_k\right],$$
$$\text{s.t. } C_{k,c}^{\mathrm{L}} \le u_{k,c} \le C_{k,c}^{\mathrm{U}}, \quad k = 1, \ldots, N, \; c = 1, \ldots, n_{u,k}. \tag{5}$$

where $\hat{\mathbf{y}}_{N|k}$ denotes the product quality at the final stage N that is predicted at stage k and $n_{u,k}$ is the dimension of the control action $\mathbf{u}_k$. The constraints $[\mathcal{C}_{k,c}^L, \mathcal{C}_{k,c}^U]$ define the upper and lower actuator limits that can be applied on each part/substage. $\mathbf{Q}_N \in \mathbf{R}^{m \times m}$ is a positive semi-definite matrix, and $\mathbf{R}_k \in \mathbf{R}^{n \times n}$ is a positive definite matrix.

This optimization index takes the form of the widely accepted cost function of a linear-quadratic regulator under the predictive control framework and thus satisfies the common requirements in control theory. Various research topics have been investigated under this framework, including the feed-forward control for multistage process, cautious control

considering model uncertainties, and actuator layout optimization in control system designs.

SoV-Enabled Product Quality and Reliability Chain Modeling and Analysis

There is a complex, intricate relationship between product quality and tooling reliability in a multistage manufacturing system. A degraded (or failed) production tool leads to a large variability in product quality and/or an excessive number of defects; on the other hand, excessive variability of product quality features accelerates the degradation and failure rates of production tooling at the station thereafter. For a multistage manufacturing system, these interactions are more complex as variations propagate from one stage to the next stage. Thus, a "chain effect" between the product quality (Q) and tooling reliability (R) can be observed and thus noted as the "QR chain" effect. Modeling of the QR chain is an integrated effort of the SoV model and the semi-Markov process model. The QR chain model plays an essential role in system reliability modeling and maintenance decisions and has led to new concepts of quality-ensured maintenance strategy, and tolerance synthesis considering tool degradation and system down time.

Summary and Future Directions

The concept of stream of variation for multistage systems can be applied to a very broad range of systems, although the existing work mostly focuses on the quality control of multistage discrete manufacturing processes. A comprehensive discussion on the stream of variation theory for a multistage manufacturing system is summarized in a monograph (Shi 2006). In addition, Shi and Zhou (2009) provides a survey of emerging methodologies for tackling various issues in multistage systems including modeling, analysis, monitoring, diagnosis, control, inspection, and design optimization.

The success of the multistage system framework in manufacturing processes will certainly stimulate the application of this framework to other systems. For example, monitoring and diagnosis of the abnormalities in throughput, cycle time, and lead time of a multistage production system are very promising application areas under the multistage system framework. The supply chain and logistics management, which involve multiple suppliers/venders in an interconnected fashion, can be treated as another multistage system with network structures. Most service systems such as health-care clinics, hospitals, and transportation systems are inherently multistage as well. It will be interesting to expand the stream of variation theory to these broadly defined multistage systems for their quality control, variation reduction, and other system-level performance improvement.

Structured Singular Value and Applications: Analyzing the Effect of Linear Time-Invariant Uncertainty in Linear Systems

Andrew Packard[1], Peter Seiler[2], and Gary Balas[2]
[1]Mechanical Engineering Department, University of California, Berkeley, CA, USA
[2]Aerospace Engineering and Mechanics Department, University of Minnesota, Minneapolis, MN, USA

Abstract

This entry presents the most commonly used formulations of robust stability and robust $\mathcal{H}_\infty$ performance for linear systems with highly structured, linear, time-invariant uncertainty. The structured singular value function (μ) is specifically defined for this purpose, involving a problem-specific set, called the *uncertainty* set. With the uncertainty set chosen, μ is a real-valued function defined on complex matrices of a fixed dimension. A few key properties are easily derived from the definition and then applied to solve the robustness analysis problem. Computation of μ, which is required to implement the analysis tests, is difficult, so computable and refinable upper and lower bounds are derived.

Keywords

Robustness analysis; Robust control; Structured uncertainty

Notation, Definition, and Properties

$\mathbf{R}$ and $\mathbf{C}$ are the real and complex numbers; $\mathbf{C}_+ = \{\gamma \in \mathbf{C} : \text{Re}(\gamma) \geq 0\}$; $\mathbf{C}^n$ is the set of $n \times 1$ vectors and $\mathbf{C}^{n \times m}$ the set of $n \times m$ matrices

Gary Balas: deceased.

with elements in $\mathbf{C}$. $\bar{\sigma}(\cdot)$ refers to the maximum singular value of a matrix; for $A \in \mathbf{C}^{n \times n}$, $\rho(A)$ is the spectral radius (largest, in magnitude, eigenvalue of A), and $\rho_{\mathbf{R}}(A)$ is the real spectral radius (largest, in magnitude, real, eigenvalue of A); $\mathcal{R}$ is the ring of proper rational functions, $\mathcal{S} = \{g \in \mathcal{R} : g \text{ has no poles in } \mathbf{C}_+\}$; $\mathcal{S}^{\bullet \times \bullet}$ denotes matrices with elements in $\mathcal{S}$, where the exact dimensions are unspecified, but clear from context; finally, no notational distinction is made between a linear system, its transfer function, and/or its frequency response function.

Let R, S, and F be nonnegative integers and $r_1, \ldots, r_R$, $s_1, \ldots, s_S$, and $f_1, \ldots, f_F$ be positive integers. Define sets $\mathbf{\Delta_R} := \{\text{diag}[\delta_1 I_{r_1}, \cdots, \delta_R I_{r_R}] : \delta_i \in \mathbf{R}\}$,

$$\mathbf{\Delta_C} := \{\text{diag}[\delta_1 I_{s_1}, \cdots, \delta_S I_{s_S}, \Delta_1, \cdots, \Delta_F] \\ : \delta_i \in \mathbf{C}, \Delta_k \in \mathbf{C}^{f_k \times f_k}\}$$

and their diagonal augmentation, $\mathbf{\Delta} := \{\text{diag}[\Delta_R, \Delta_C] : \Delta_R \in \mathbf{\Delta_R}, \Delta_C \in \mathbf{\Delta_C}\} \subseteq \mathbf{C}^{n \times n}$. The set $\mathbf{\Delta}$ is called the *block structure*. The block structure can be generalized to handle nonsquare blocks in $\mathbf{\Delta_C}$ at the expense of additional notation. If $R = 0$, then $\mathbf{\Delta}$ is called a *complex* block structure. If $S = F = 0$, then $\mathbf{\Delta}$ is called a *real* block structure. For $M \in \mathbf{C}^{n \times n}$, $\mu_{\mathbf{\Delta}}(M)$ is defined as

$$\mu_{\mathbf{\Delta}}(M) := \frac{1}{\min\{\bar{\sigma}(\Delta) : \Delta \in \mathbf{\Delta}, \det(I - M\Delta) = 0\}}$$

unless no $\Delta \in \mathbf{\Delta}$ makes $I - M\Delta$ singular, in which case $\mu_{\mathbf{\Delta}}(M) := 0$, (Doyle 1982; Safonov 1982). The function $\mu_{\mathbf{\Delta}}(\cdot) : \mathbf{C}^{n \times n} \to \mathbf{R}$ is upper semicontinuous. Following Fan et al. (1991), the constraint set in the definition can be written as $\{\bar{\sigma}(\Delta) : \exists w, z \in \mathbf{C}^n, w = Mz, z = \Delta w, w \neq 0_n\}$, so that without loss of generality, at the minimum, the elements $\Delta_1, \ldots, \Delta_F$ each have rank equal to 1. For specific block structures, simplifications occur: if $R = S = 0$ and $F = 1$, then $\mu_{\mathbf{\Delta}}(M) = \bar{\sigma}(M)$; if $R = F = 0$ and $S = 1$, then $\mu_{\mathbf{\Delta}}(M) = \rho(M)$; and if $S = F = 0$ and $R = 1$, then $\mu_{\mathbf{\Delta}}(M) = \rho_{\mathbf{R}}(M)$. In general $\rho_{\mathbf{R}}(M) \leq \mu_{\mathbf{\Delta}}(M) \leq \bar{\sigma}(M)$. Associated with $\mathbf{\Delta}$ define $\mathbf{B_\Delta} := \{\Delta \in \mathbf{\Delta} : \bar{\sigma}(\Delta) \leq 1\}$. Since

S

$I - M\Delta$ is singular if and only if $M\Delta$ has an eigenvalue exactly equal to 1, it follows that $\mu_{\Delta}(M) = \max_{\Delta \in \mathbf{B}_{\Delta}} \rho_{\mathbf{R}}(M\Delta)$. If Δ is a complex block structure, then $\rho_{\mathbf{R}}(\cdot)$ can be replaced with $\rho(\cdot)$, and in that case $\mu_{\Delta}(\cdot) : \mathbf{C}^{n \times n} \to \mathbf{R}$ is continuous.

A common application is to quantify the effect (in structured singular value terms) that an uncertain matrix Δ has on the expression $F_L(M, \Delta) := M_{11} + M_{12}\Delta(I - M_{22}\Delta)^{-1}M_{21}$, a *linear fractional transformation* (LFT) of Δ by M. This is conceptually straightforward (informally called the *main loop theorem*) using the Schur formula for determinants. Specifically, let $\mathbf{\Delta_1} \subseteq \mathbf{C}^{n_1 \times n_1}$, $\mathbf{\Delta_2} \subseteq \mathbf{C}^{n_2 \times n_2}$ be block structures Δ and $\subseteq \mathbf{C}^{(n_1+n_2) \times (n_1+n_2)}$ be their block-diagonal augmentation. For $M \in \mathbf{C}^{(n_1+n_2) \times (n_1+n_2)}$, $\mu_{\Delta}(M) < 1$ if and only if $\mu_{\Delta_2}(M_{22}) < 1$ and

$$\max_{\Delta_2 \in \mathbf{B}_{\Delta_2}} \mu_{\Delta_1}(F_L(M, \Delta_2)) < 1.$$

Finally (Packard and Pandey 1993) if $\mathbf{\Delta_1}$ is a block structure, and $\mathbf{\Delta_2}$ is a complex block structure, and M satisfies $\mu_{\Delta_1}(M_{11}) < \mu_{\Delta}(M)$, then $\mu_{\Delta}(\cdot)$ is continuous on an open ball around M. Loosely speaking, "if there are any complex blocks, and M is such that they matter, then μ is continuous at M." This means that at points of discontinuity, only $\Delta_R \in \mathbf{\Delta_R}$ need to be nonzero. For any polynomial $p : \mathbf{C}^n \to \mathbf{C}$, there is a minimum-norm root (using $\|\cdot\|_{\infty}$ on $\mathbf{C}^n$) whose components all have equal modulus (Doyle 1982). Defining

$$\mathbf{Q_{\Delta}} := \{\mathrm{diag}[\Delta_R, \Delta_C] : \bar{\sigma}(\Delta_R) \leq 1, \Delta_C^* \Delta_C = I\}$$

and employing this result (Young and Doyle 1997) derives that $\mu_{\Delta}(M) = \max_{Q \in \mathbf{Q_{\Delta}}} \rho_{\mathbf{R}}(MQ)$. This gives a generalized maximum-modulus-like theorem for LFTs (Packard and Pandey 1993). Revisiting the setup for the main loop theorem, assume further that $\mathbf{\Delta_2}$ is a complex block structure. If $\mu_{\Delta_2}(M_{22}) < 1$, then

$$\max_{\Delta_2 \in \mathbf{B}_{\Delta_2}} \mu_{\Delta_1}(F_L(M, \Delta_2)) = \max_{Q_2 \in \mathbf{Q}_{\Delta_2}} \mu_{\Delta_1}(F_L(M, Q_2)).$$

This leads to specialized results per Boyd and Desoer (1985), Packard and Pandey (1993), and Tits and Fan (1995) for stable transfer function matrices. For any block structure $\mathbf{\Delta} \subseteq \mathbf{C}^{n \times n}$ and $M \in \mathcal{S}^{n \times n}$, then

$$\max\left\{\sup_{\omega \in \mathbf{R}} \mu_{\Delta}(M(j\omega)), \mu_{\Delta}(M(\infty))\right\}$$

$$= \max\left\{\sup_{s \in \mathbf{C}_+} \mu_{\Delta}(M(s)), \mu_{\Delta}(M(\infty))\right\}.$$

Robustness of Stability and Performance

There are several uncertain system formulations that all result in the same μ-analysis test to assess the robustness of stability and/or performance (Wall et al. 1982; Foo and Postlethwaite 1988). In this article, we present the simplest and most common interpretation. Consider an interconnection of known systems, $\{G_i\}_{i=1}^{M}$, and unknown systems $\{\Gamma_k\}_{k=1}^{N}$, as described by

$$\begin{bmatrix} q_1 \\ e \\ q_2 \end{bmatrix} = H \begin{bmatrix} z_1 \\ d \\ z_2 \end{bmatrix}$$

where $z_1 = \mathrm{diag}[G_1, \ldots, G_M](q_1 + w_1)$, $z_2 = \mathrm{diag}[\Gamma_1, \ldots, \Gamma_N](q_2 + w_2)$, and $H \in \mathbf{R}^{(n_1+n_e+n_2) \times (p_1+n_d+p_2)}$ (naturally partitioned as a block 3-by-3 array). This is depicted in Fig. 1. Each G_i and Γ_k is assumed to be a finite-dimensional, time-invariant linear system, with proper transfer function, and a stabilizable and detectable internal state-space description.

The interconnection is *well posed* if for any initial conditions and any (say) piecewise continuous inputs w_1, w_2, and d, there exist unique solutions to the interconnection equations. By manipulating the state-space or transfer function descriptions of a well-posed interconnection, a state-space model or proper transfer function description for the map from (d, w) to (e, z) can be derived. A well-posed interconnection is *stable* if the resultant state-space model is internally stable – the eigenvalues of its "A" matrix are in
Structured Singular Value and Applications: Analyzing the Effect of Linear Time-Invariant Uncertainty in Linear Systems, Fig. 1 Interconnection of $G_1, \ldots, G_M, \Gamma_1, \ldots, \Gamma_N$

the open, left-half plane. Given some restrictions on the values of the elements of Γ, *robustness analysis* poses the question: is the interconnection well posed and stable for all possible values of Γ? And if so, then is the $\|\cdot\|_\infty$ gain from d-to-$e \le 1$ for all possible values of Γ? The goal of the analysis is to confirm "yes" or supply a particular Γ which proves that the answer is "no" (by rendering the interconnection ill-posed, unstable, or with d-to-e gain >1). Standard linear systems theory gives that the interconnection is well posed if and only if

$$\det\left(I - \begin{bmatrix} H_{11} & H_{13} \\ H_{31} & H_{33} \end{bmatrix}\begin{bmatrix} G(\infty) & 0 \\ 0 & \Gamma(\infty) \end{bmatrix}\right) \ne 0,$$

and that the interconnection is stable if and only if the transfer function matrix $T^{w,z}$, mapping $[w_1; w_2]$ to $[z_1; z_2]$, is an element of $\mathcal{S}^{\bullet \times \bullet}$.

The assumptions on each Γ_k are of three kinds: (i) Γ_k is a stable linear system, known only to satisfy $\|\Gamma_k\|_\infty < 1$; (ii) Γ_k is a stable linear system of the form $\gamma_k I$, where the scalar linear system γ_k is known to satisfy $\|\gamma_k\|_\infty < 1$; (iii) Γ_k is a constant gain, of the form $\gamma_k I$, where the scalar $\gamma_k \in \mathbf{R}$ is known to satisfy $-1 < \gamma_k < 1$. Note the similarity between this and the block structure $\boldsymbol{\Delta}$ (via $\boldsymbol{\Delta_R}$ and $\boldsymbol{\Delta_C}$) introduced earlier. After rearrangement, this block-diagonal augmentation of uncertain systems is a norm-bounded (by 1) element of the set

$$\boldsymbol{\Gamma} := \{\operatorname{diag}[\Gamma_R, \Gamma_U] : \Gamma_R \in \boldsymbol{\Delta_R}, \Gamma_U \in \mathcal{S}^{\bullet \times \bullet},$$
$$\Gamma_U(s_0) \in \boldsymbol{\Delta_C} \; \forall s_0 \in \mathbf{C_+}\}.$$

Since 0 is a possible value of Γ, two necessary conditions (denoted c.1 and c.2, respectively) for robust well-posedness and stability are at $\Gamma = 0$, specifically $\det(I - G(\infty)H_{11}) \ne 0$ and $V := G(s)(I - H_{11}G(s))^{-1} \in \mathcal{S}^{\bullet \times \bullet}$. Assuming $\det(I - G(\infty)H_{11}) \ne 0$ (i.e., c.1), the Schur formula for block determinants reduces the well-posedness condition to

$$\det\left(I - \Gamma(\infty)\left[H_{33} + H_{31}(I - G(\infty)H_{11})^{-1}\right.\right.$$
$$\left.\left. G(\infty)H_{13}\right]\right) \ne 0.$$

Define $M := H_{33} + H_{31}G(I - H_{11}G)^{-1}H_{13} \in \mathcal{S}^{\bullet \times \bullet}$, and $X := I - \Gamma M$. Then

$$T^{w,z} = \begin{bmatrix} V + VH_{13}X^{-1}\Gamma H_{31}V & VH_{13}X^{-1}\Gamma \\ X^{-1}\Gamma H_{31}V & X^{-1}\Gamma \end{bmatrix}$$

Assuming c.2, namely, $V \in \mathcal{S}^{\bullet \times \bullet}$, then $X^{-1} \in \mathcal{S}^{\bullet \times \bullet}$ implies that $T^{w,z} \in \mathcal{S}^{\bullet \times \bullet}$ – moreover $T^{w,z} \in \mathcal{S}^{\bullet \times \bullet}$ implies that $X^{-1} = I + T_{22}^{w,z}M \in \mathcal{S}^{\bullet \times \bullet}$. Finally, since both M and Γ are stable, it follows that $X^{-1} \in \mathcal{S}^{\bullet \times \bullet}$ if and only if $\det(I - M(s_0)\Gamma(s_0)) \ne 0 \quad \forall s_0 \in \mathbf{C_+}$. The maximum-modulus property gives the robustness theorem. With the definition of M and conditions c.1 and c.2, the uncertain system is robustly stable and well posed if and only if

$$\max\left\{\sup_{\omega \in \mathbf{R}} \mu_{\boldsymbol{\Delta}}(M(j\omega)), \mu_{\boldsymbol{\Delta}}(M(\infty))\right\} \le 1.$$

Indeed, if the condition holds, then by maximum-modulus theorem and the definition of μ, it follows that $\det(I - M(s)\Gamma(s)) \ne 0$ for all $s \in \mathbf{C_+}$ as well as $s = \infty$, since $\Gamma(s) \in \boldsymbol{\Delta}$ and $\bar{\sigma}(\Gamma(s)) < 1$. This gives well-posedness and stability for all such Γ, as desired (an alternate proof, using the Nyquist criterion is also common). Conversely, if the condition is violated, then at some frequency (0, nonzero, or ∞), μ is larger than 1, as evidenced by a (constant matrix) $\Delta \in \boldsymbol{\Delta} \subseteq \mathbf{C}^{n \times n}$, $\bar{\sigma}(\Delta) < 1$, which causes singularity. If the frequency is nonzero (and finite),

S

the interpolation lemmas in the appendix enable replacing the complex blocks with stable, real-rational entries. Otherwise (0 or ∞), the matrix is such that μ is continuous, and hence a finite, nonzero frequency also has $\mu > 1$, or only the real blocks are necessary to cause singularity. In all cases, $\Gamma \in \boldsymbol{\Gamma}$ with $\|\Gamma\|_{\infty} < 1$ exists to cause ill-posedness or instability (Tits and Fan 1995).

Robustness of performance, measured as $\|T^{e,d}\|_{\infty}$, can be addressed, using the main loop theorem, and an additional complex full block (recall $\bar{\sigma}(\cdot) = \mu_{\boldsymbol{\Delta}}(\cdot)$ when $F = 1$, $S = R = 0$). Define

$$M_P := \begin{bmatrix} H_{22} & H_{23} \\ H_{32} & H_{33} \end{bmatrix} + \begin{bmatrix} H_{21} \\ H_{31} \end{bmatrix}$$
$$G(I - H_{11}G)^{-1} \begin{bmatrix} H_{12} & H_{13} \end{bmatrix}$$

and $\boldsymbol{\Delta}_P := \{\operatorname{diag}[\Delta_P, \Delta] : \Delta_P \in \mathbf{C}^{n_d \times n_e}, \Delta \in \boldsymbol{\Delta}\}$. With conditions c.1 and c.2, the uncertain system is robustly stable and well posed and satisfies $\|T^{e,d}\|_{\infty} \leq 1$ if and only if

$$\max \left\{ \sup_{\omega \in \mathbf{R}} \mu_{\boldsymbol{\Delta}_P}(M_P(j\omega)), \mu_{\boldsymbol{\Delta}_P}(M_P(\infty)) \right\} \leq 1.$$

Computations

The robust stability and robust performance theorems require computing μ on the frequency response function $M(j\omega)$. Computing μ is known to be a computationally difficult problem (Toker and Ozbay 1998), so exact computational methods are generally not pursued. Reliable algorithms have been developed which yield upper and lower bounds, which are often sufficiently close for many engineering problems.

Lower Bounds

Recall that $\mu_{\boldsymbol{\Delta}}(M) = \max_{\Delta \in \mathbf{B}_{\boldsymbol{\Delta}}} \rho_{\mathbf{R}}(M\Delta) = \max_{Q \in \mathbf{Q}_{\boldsymbol{\Delta}}} \rho_{\mathbf{R}}(MQ)$. Practically speaking, these maximizations yield lower bounds for $\mu_{\boldsymbol{\Delta}}(M)$, since the global maximum may not be attained. In addition to gradient-based ascent methods, the optimality conditions for $Q \in \mathbf{Q}_{\boldsymbol{\Delta}}$ to be a local maximum of the function $\rho_{\mathbf{R}}(M\Delta)$ on the set

$\mathbf{B}_{\boldsymbol{\Delta}}$ can be derived (Young and Doyle 1997). A solution approach, similar to a Jacobi iteration, leads to an iteration that resembles combinations of the familiar power methods for spectral radius and maximum singular value. If the iteration converges (which is not guaranteed), a lower bound for $\mu_{\boldsymbol{\Delta}}(M)$ (along with a corresponding $\Delta \in \boldsymbol{\Delta}$) is produced. Studies with matrices constructed to have $\mu_{\boldsymbol{\Delta}}(M) = 1$ suggest that the iteration is very reliable for complex block structures, though usually quite poor for purely real block structures. There are several, more computationally demanding algorithms available for purely real block structures (de Gaston and Safonov 1988; Sideris and Sanchez Pena 1989). For the common situation, with both real and complex blocks, where continuity is assured, the power algorithm generally has adequate performance.

Upper Bounds

Define $\mathbf{G}_{\boldsymbol{\Delta}} := \{G = -G^* : G\Delta = -\Delta^* G^* \ \forall \Delta \in \boldsymbol{\Delta}\}$, $\mathbf{D}_{\boldsymbol{\Delta}} := \{D = D^* \succ 0 : D\Delta = \Delta D \ \forall \Delta \in \boldsymbol{\Delta}\}$, subsets of $\mathbf{C}^{n \times n}$. Elements of $\mathbf{D}_{\boldsymbol{\Delta}}$ are of the form $\operatorname{diag}[D_{r_1}, \ldots, D_{r_R}, D_{s_1}, \ldots, D_{s_S}, d_1 I_{f_1}, \ldots, d_F I_{f_F}]$, and therefore $D \in \mathbf{D}_{\boldsymbol{\Delta}}$ implies that $D^{\frac{1}{2}} \in \mathbf{D}_{\boldsymbol{\Delta}}$ too. Likewise,

$$\mathbf{G}_{\boldsymbol{\Delta}} := \{\operatorname{diag}[G_R, 0] : G_R = -G_R^* \in \mathbf{C}^{\bullet \times \bullet},$$
$$G_R \Delta_R = \Delta_R G_R \ \forall \Delta_R \in \boldsymbol{\Delta}_{\mathbf{R}}\}.$$

A concise derivation (Helmersson 1995) verifies the upper bound formula (Fan et al. 1991). If $\beta > 0$, $G \in \mathbf{G}_{\boldsymbol{\Delta}}$, and $D \in \mathbf{D}_{\boldsymbol{\Delta}}$ satisfy $M^*DM - \beta^2 D + GM + M^*G^* \preceq 0$, then $\mu_{\boldsymbol{\Delta}}(M) \leq \beta$. Indeed, if $\Delta \in \boldsymbol{\Delta}$ has $\det(I - M\Delta) = 0$, there exist nonzero $w, z \in \mathbf{C}^n$ with $w = Mz$, $z = \Delta w$. Certainly $z^*(M^*DM - \beta^2 D + GM + M^*G^*)z \leq 0$. Making substitutions gives

$$0 \geq w^*Dw - \beta^2 w^* \Delta^* D\Delta w$$
$$+ w^* \Delta^* Gw + w^* G^* \Delta w$$
$$= w^*Dw - \beta^2 w^* D^{\frac{1}{2}} \Delta^* \Delta D^{\frac{1}{2}}$$
$$w + w^* \Delta^* Gw - w^* \Delta^* Gw$$
$$= w^* D^{\frac{1}{2}} \left(I - \beta^2 \Delta^* \Delta\right) D^{\frac{1}{2}} w.$$

Since D is invertible and $w \neq 0_n$, it must be that $\bar{\sigma}(\Delta) \geq \beta^{-1}$, as desired. The constraint $M^*DM - \beta^2 D + GM + M^*G^* \preceq 0$ is a linear matrix inequality (LMI) in the variables D and G. Minimizing β over $G \in \mathbf{G_\Delta}$ and $D \in \mathbf{D_\Delta}$ subject to the LMI constraint (using Boyd and El Ghaoui 1993, for instance) yields the best upper bound that this inequality can produce.

Further Perspectives

The robustness tests involve bounding $\mu_{\mathbf{\Delta}}(M(j\omega))$ over the entire real axis. A common approach is to use a dense frequency gridding and upper/lower bound calculations at each gridded point. The advantages, simplicity and trivial parallelization, are offset with disadvantages, in that the peak value (over $\mathbf{R}$) may not be reflected accurately by the peak across the finite grid. In fact, such a grid-based test determines the smallest $\Delta \in \mathbf{\Delta}$ which can cause a pole to migrate from the left-half plane into the right-half plane *at exactly one of the frequency grid points* (as opposed to any location). Nevertheless, with some continuity assurances in place and a dense grid, this is often adequate knowledge for most engineering decisions. However, the brute-force grid approach can be avoided by treating the frequency-variable (ω) as an additional real parameter (since $M(j\omega)$ is an LFT of $\frac{1}{\omega}$) (Ferreres et al. 2003). This is a generalization of the Hamiltonian methods to compute the $\mathcal{H}_\infty$ norm of a linear system without a frequency grid, coupled with an alternative form of the upper bound (Young et al. 1995). Moreover, if only the peak value (upper bound, say) across frequency is desired, this approach can be fast, as some calculations rule out large frequency ranges to not contain the peak.

Improved upper bounds can be derived using higher-order arguments, changing the LMI constraint into a sum-of-squares constraint (which ultimately is just a larger LMI). Alternatively, branch-and-bound techniques are especially useful at reducing the conservativeness of the (D, G) upper bound when there are several real parameters ($R > 0$) (Newlin and Young 1997).

Appendix: Interpolation Lemmas

Two interpolation lemmas make the connection between robustness to constant-gain, complex-valued uncertainties ($\mathbf{\Delta}$) and stable, finite-dimensional, time-invariant linear systems described by ODEs with real coefficients ($\mathbf{\Gamma}$). Lemma 1 is used (block by block and element by element on the relevant vector directions within each block) to interpolate complex blocks causing singularity into real-rational blocks which cause singularity at a particular frequency.

Lemma 1 *Given a positive $\bar{\omega} > 0$ and a complex number δ, with $\text{Imag}(\delta) \neq 0$, there is a $\beta > 0$ such that by proper choice of sign $\pm |\delta| \left. \frac{s-\beta}{s+\beta} \right|_{s=j\bar{\omega}} = \delta$.*

Lemma 2 *Suppose $M \in \mathbf{C}^{n \times n}$ and $\bar{\omega} > 0$. If $\Delta \in \mathbf{\Delta}$ satisfies $\det(I_n - M\Delta) = 0$, then there is a $\Gamma \in \mathbf{\Gamma}$ with $\|\Gamma\|_\infty \leq \bar{\sigma}(\Delta)$ and $\det(I_n - M\Gamma(j\bar{\omega})) = 0$.*

Summary and Future Directions

The structured singular value, μ, is a linear algebra construct, defined to exactly deal with linear, time-invariant uncertainty in linear systems. The main issues are computational, focused on efficient manners to compute reasonably tight upper and lower bounds at each frequency and, more specifically, ascertain the peak value across frequency. Alternatives to the worst-case approach to robustness analysis are gaining favor and may be applicable in analysis and design situations where the abstraction of a worst-case view is too conservative (Calafiore et al. 2000).

Sub-Riemannian Optimization

Roger Brockett
Harvard University, Cambridge, MA, USA

Abstract

Optimization problems arising in the control of some important types of physical systems lead naturally to problems in sub-Riemannian optimization. Here we provide context and background material on the relevant mathematics and discuss some specific problem areas where these ideas play a role.

Keywords

Carnot-Carathéodory metric; Lie algebras; Periodic processes; Subelliptic operators; Sub-Riemannian geodesics; Symmetric spaces

Introduction

After a start in the early 1970s, over the last two decades, sub-Riemannian geometry and the related theory of subelliptic operators have become popular topics in the control literature. Their study is sometimes linked to questions involving the dynamics and control of mechanical systems with nonholonomic (nonintegrable) constraints and the use of what has classically been called quasi-coordinates because both subjects depend on Lie algebraic techniques. However, here we limit ourselves to problems in sub-Riemannian optimization per se, describing how they arise in various areas of physics and engineering. Most famously, the second law of thermodynamics, as recast by Carathéodory in differential geometric form, provides an example of the reach of sub-Riemannian geometry into the engineering world.

The statement of control theoretic problems often begins with a description of the system of interest in differential equation form:

$$\dot{x} = f(x) + \sum u_i g_i(x) \; ; \; x \in X, u \in \mathbb{R}^m$$

with X an n-dimensional manifold. In well-motivated control problems, n is almost always larger than m; the dimension of the space of controls is less than the dimension of the state space. In the case of mechanical systems, the phrase *under actuated* is sometimes used to characterize this, but the situation is ubiquitous. The analysis is complicated by presence of the immutable *drift term* f. When it is desired to use an optimization principle to find a good choice for u, one introduces a performance measure, often of the form

$$\eta = \int_0^{t_1} L(x, u) \; dt$$

and attempts to minimize η subject to whatever constraints there may be on u and x. If there is no drift term and if the Lie algebra generated by $\{g_1, g_2, \cdots, g_m\}$ defines a distribution that spans the tangent space of X at every point, the problem falls under the purview of *sub-Riemannian geometry*. In this case, one can describe the situation as $\dot{x} = G(x)u$ with G being an x-dependent rectangular matrix of rank m everywhere.

This entry is written from a control theory point of view. The problems discussed here provided the impetus for some later mathematical work, often not discussing the motivation. The purely mathematical work is de-emphasized here, much as the mathematical work often gives little or no attention to the control theoretic work that preceded it.

The Distance Function

A prototype control problem leading to sub Riemannian geometry is that of steering the system $\dot{x}_1 = u_1 \; \dot{x}_2 = u_2 \; \dot{x}_3 = x_1 u_2 - x_2 u_1$ from one state to another while minimizing

$$\eta = \int_0^1 \sqrt{u_1^2 + u_2^2} \; dt$$

It might seem that this is just a minor change from a standard shortest path problem in Riemannian geometry, e.g., it might be thought as a limiting case of a standard Riemannian geodesic problem in which the infinitesimal length is given by

$$(ds)^2 = \begin{bmatrix} dx_1 & dx_2 & dx_3 \end{bmatrix} \begin{bmatrix} 1 & 0 & -y \\ 0 & 1 & x \\ -y & x & \epsilon + x^2 + y^2 \end{bmatrix}^{-1} \begin{bmatrix} dx_1 \\ dx_2 \\ dx_3 \end{bmatrix}$$

and ϵ is allowed to go to zero. However, because when ϵ equals zero this matrix is singular, it cannot be used to define the equations for geodesics. The most direct attack seems to be to use a Lagrange multiplier to enforce the condition on x_3, which leads to the minimization of

S

$$\eta = \int_0^1 \dot{x}_1^2 + \dot{x}_2^2 + \lambda(x_1\dot{x}_2 - x_2\dot{x}_1) \, dt$$

This yields a set of λ-dependent linear equations for x_1 and x_2. Solving these shows that the projections of the minimum length trajectories onto the (x_1, x_2)-plane are circular arcs.

In Riemannian geometry, the set of points which are of distance r from a given point will, for r sufficiently small, form a co-dimension one manifold diffeomorphic to a sphere. In this qualitative sense, Riemannian spaces are locally isotropic. In sub-Riemannian geometry, the set of points of distance $r > 0$ from a distinguished point x_0 does not have such a simple structure. For example, for the problem just discussed, we have the approximations

$$d = \sqrt{x_1^2 + x_2^2} + |x_3|/(x_1^2 + x_2^2)$$
$$\text{for } |x_3| \ll (x_1^2 + x_2^2)$$

and

$$d = 2\pi|x_3| - \sqrt{8\pi(x_1^2 + x_2^2)|x_3|}$$
$$\text{for } \sqrt{x_1^2 + x_2^2} \ll |x_3|$$

That is, for points bounded by paraboloids, defining a region near the (x_1, x_2)-plane, the distance is close to the Riemannian distance, whereas in a cone containing the x_3 axis, the distance is close to the square root of the Riemannian distance. These approximations make it clear that $d(x_1, x_2, x_3)$ is not differentiable at points on the x_3 axis. There is much more that can be said here. One interesting topic concerns the number of trajectories that satisfy the first-order necessary conditions and join a point to the origin.

More Examples

Consider the kinematic equations of the unicycle. If (x, y) are the coordinates of the center of the wheel and θ is the heading angle, then these are

$$\dot{x} = \cos\theta u_2 \; ; \; \dot{y} = \sin\theta u_2 \; ; \; \dot{\phi} = u_1$$

It is of interest to generate a "shortest path" between two points in (x, y, θ)-space where shortest is defined as the integral of some function of x, y, θ, u_1, u_2. This is typical of the kind of path planning problems in which nonholonomic constraints lead to sub-Riemannian problems. A variety of such problems arise in robotics with optimal steering programs for cars being one example.

As an example involving a compact manifold, let X be the space of 3-by-3 orthogonal matrices and consider the system described by

$$\dot{x} = \begin{bmatrix} 0 & u_1 & u_2 \\ -u_1 & 0 & 0 \\ -u_2 & 0 & 0 \end{bmatrix} x$$

In this case, the manifold X is three dimensional and the control space is two dimensional. If we wish to minimize the integral of $u^2 + v^2$ subject to $x(0) = x_0$ and $x(1) = x_1$, we have a typical sub-Riemannian geodesic problem.

If the controls contain random effects, efforts to analyze the situation lead to related problems in stochastic process. The most widely studied of these are described by an Itô equation of the form

$$dx = f(x)dt + \sum g_i(x)dw_i$$

The corresponding equation for the evolution of the probability density $\rho(t, x)$ can be put in the form

$$\frac{\partial\rho}{\partial t} = \sum a_i(x)\frac{\partial}{\partial x_i}\rho(t, x)$$
$$+ \sum b_{ij}(x)\frac{\partial}{\partial x_i}\frac{\partial}{\partial x_j}\rho(t, x)$$

However, rather than the right-hand side being a fully elliptic operator, as it would be in a typical heat equation (e.g., the Laplace-Beltrami operator), the symmetric matrix $B(x) = b_{ij}(x)$ is singular. If the g_i satisfy the bracket-generating condition, the density equation is said to be *subelliptic*. The system described by the Itô equation

$$\begin{bmatrix} dx_1 \\ dx_2 \\ dx_3 \end{bmatrix} = \begin{bmatrix} -dt & dw_1 & dw_2 \\ -dw_1 & -dt/2 & 0 \\ -dw_2 & 0 & -dt/2 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix}$$

evolves on the two-sphere and the spectrum of the subelliptic operator is discrete. The diffusion time constants, i.e., the eigenvalues of the subelliptic operator, can be computed explicitly and compared with those of the fully elliptic operator, i.e., the standard Laplacian on the spherical shell.

Much has been written on the ways in which subelliptic diffusion does, and does not, share the properties of the ordinary diffusion equation.

A Special Structure

A rich, and especially tractable, class of sub-Riemannian problems come from the following situation. Suppose that $\mathcal{G}$ is a Lie group with Lie algebra G and that $\mathcal{H}$ is a closed subgroup with Lie algebra H. According to one definition, the pair $\mathcal{H} \subset \mathcal{G}$ is said to define a *symmetric space* if the Lie algebra G, viewed as a vector space, is the direct sum of H and K with $[H, K] \subset K$ and $[K, K] \subset H$. Let x evolve in $\mathcal{G}$ as

$$\dot{x} = ux \; ; \; x \in \mathcal{G} \; ; \; u \in K$$

For the sake of exposition, suppose that $\mathcal{G}$ is a matrix Lie group. We look for paths joining x_0 and x_1 that are shortest in the sense that

$$\eta = \int_0^1 ||u|| \, dt \; ;$$

is minimized, where $||u||^2 = \text{tr}(u^T u)$. (This leads to the same trajectories as those which minimize the integral of $||u||^2$.) To find the first-order necessary conditions using the maximum principle, define a Hamiltonian as $h(x, p, u) = \text{tr}(p^T ux + u^T u)$. Thus, $\dot{p} = -u^T p$ and minimizing over u implies $2u = -\pi_1(xp^T)$ where π_1 is the projection onto K. The product $m = xp^T$ satisfies $\dot{m} = [m, \pi_1(m)]$. Using the structural properties of the Lie algebra, we see that $(d/dt)\pi_0(m) = 0$ and that $(d/dt)\pi_1(m) = [\pi_1(m), m_0]$. Working out the implications, we see that trajectories of the

form $x(t) = e^{at} e^{(b-a)t}$ with $a \in H$ and $b \in K$ satisfy the first-order optimality conditions.

To illustrate, we consider the generalization of an earlier example. Let X be the space of n-by-n orthogonal matrices and consider the system described by

$$\dot{x} = \begin{bmatrix} 0 & u_1 & u_2 & \cdots & u_{n-1} \\ -u_1 & 0 & 0 & \cdots & 0 \\ -u_2 & 0 & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & \cdots & \vdots \\ -u_{n-1} & 0 & 0 & \cdots & 0 \end{bmatrix} x$$

Here the role of H is played by the sub-algebra of the set of real n-by-n skew-symmetric matrices consisting those whose first row and column vanish and K consists of the subset whose lower-right $(n-1)$-by-$(n-1)$ sub-matrix vanishes. In this case, the paths satisfying the first-order necessary conditions take the form $x(t) = e^{ht} e^{(k-h)t} x(0)$.

Nonintegrability and Cyclic Processes

Of course *nonintegrable* stands in opposition to the word *integrable*, as it is used in the consideration of integration performed along paths, e.g.,

$$I = \int_\gamma g_1(x)dx_1 + g_2(x)dx_2 + \cdots + g_n(x)dx_n$$

If the path γ starts at $\bar{x}$ and ends at $\hat{x}$, then the equality of mixed partials $\partial g_i/\partial x_j = \partial g_j/\partial x_i$ implies that along any two paths with these end points, the integral has the same value, provided that one of the paths can be continuously deformed into the other with the g_i being well defined along the deformation. In particular, if γ is a closed curve so $\bar{x} = \hat{x}$, then under these assumptions, the integral is zero.

On the other hand, there is a large list of important processes in biology and engineering, such as those involving the thermodynamic cycles of internal combustions engines or air conditioners, that depend critically on nonintegrable effects. These include cyclic phenomena such as

walking and breathing and a widely used mechanisms for efficient voltage conversion in electrical engineering. Thus, both nature and technology provide examples of processes in which the pistons, valves, etc. move along a smooth path and at the end of a cycle return to their initial configuration, while a related integral is not zero. Perhaps, the best-known path problem of this type is the Carnot cycle.

Questions about sub-Riemannian optimization enter here both as the optimization of the path defining the cycle and in the optimal regulation of the output of such cyclic processes. In general, the output can adjust both the amplitude and frequency of the cycle (volume of air per cycle and respiration rate), although in some cases one or the other of these might be fixed. For example, cruise control for automobiles regulates the frequency (rpm) of the engine but cannot adjust the stroke length of the pistons, whereas speed control of a running animal ordinarily involves adjusting both the length of the stride and the "steps" per minute. The primary considerations for these control processes are stability and response time, with the shape of the cycles being determined by some measure of efficiency. It seems that the optimization of such regulatory processes deserves more attention.

Subspace Techniques in System Identification

Michel Verhaegen
Delft Center for Systems and Control, Delft University, Delft, The Netherlands

Abstract

An overview is given of the class of subspace techniques (STs) for identifying linear, time-invariant state-space models from input-output data. STs do not require a parametrization of the system matrices and as a consequence do not suffer from problems related to local minima that often hamper successful application of parametric optimization- based identification methods.

The overview follows the historic line of development. It starts from Kronecker's result on the representation of an infinite power series by a rational function and then addresses, respectively, the deterministic realization problem, its stochastic variant, and finally the identification of a state-space model given in innovation form.

The overview summarizes the fundamental principles of the algorithms to solve the problems and summarizes the results about the statistical properties of the estimates as well as the practical issues like choice of weighting matrices and the selection of dimension parameters in using these STs in practice. The overview concludes with probing some future challenges and makes suggestions for further reading.

Keywords

Extended observability matrix; Hankel matrix; Innovation model; State-space model; Singular value decomposition (SVD)

Introduction

Subspace techniques (STs) for system identification address the problem of identifying state-space models of MIMO dynamical systems. The roots of ST were laid by the German mathematician Leopold Kronecker (°1823–†1891). In Kronecker (1890) Kronecker established that a power series could be represented by a rational function when the *rank of the Hankel* operator with that power series as its symbol was *finite*. In the early 1990s of the twentieth century, new generalizations of the idea of Kronecker were presented for identifying linear, time-invariant (LTI) state-space models from input-output data or output data only. These new generalizations were formulated from different perspectives, namely, within the context of canonical variate analysis (Larimore 1990), within a linear algebra context (Van Overschee and De Moor 1994; Verhaegen 1994), and subspace splitting (Jansson and Wahlberg 1996). Despite their different origin, the close relationship between these methods was quickly established by a unifying theorem that

interpreted these methods as a singular value decomposition (SVD) of a weighted matrix from which an estimate of the column space of the observability matrix or the row space of the state sequence of the given system or Kalman filter for observing the state of that system is derived (Van Overschee and De Moor 1995). This subspace calculation is the key feature that leads to the indication by ST for system identification or subspace identification methods (SIM).

The STs are attractive *complementary* techniques to the maximum likelihood or prediction error framework. They do not require the user to specify a parametrization of the system matrices of the state-space model, and the user is not confronted with the problems due to possible local minima of a nonlinear parameter optimization method that is often necessary in estimating the parameters of a state-space model via, e.g., prediction error methods. Though the statistical properties such as consistency and efficiency have been investigated, such as in Bauer and Ljung (2002), the estimates obtained via ST are in general not optimal in the statistical minimum variance sense. However, practical evidence with the use of ST in a wide variety of problems has indicated that ST provides accurate estimates. As such they are often used as an initialization to the maximum likelihood or prediction error parametric identification methods.

In this chapter we make a distinction between *output only* or stochastic identification problems and *input–output* or combined deterministic-stochastic identification problems. The first occurs when identifying, e.g., the eigenmodes of a bridge from ambient acceleration responses of the bridge. The second occurs when, in addition to ambient excitations that cannot be directly measured, controlled excitations through actuators integrated in the system are used during the collection of the input–output data.

The outline of this chapter is as follows. In the next section, we formulate the LTI state-space model identification problems and outline the general strategy of ST. The presentation of ST is given according to the historical development of ST. It starts with a summary of the solution to the deterministic realization problem, which

S

considers the noise-free "impulse" response of the system. Subsequently we present the stochastic realization problem which considers the output-only identification problem where the output is assumed to be a filtered zero-mean, white-noise sequence. The ST solution is discussed assuming samples of the covariance function of the output to be given. The deterministic-stochastic identification problem is considered in section "Combined Deterministic-Stochastic ST." In this section we first consider open-loop identification experiments. For this case, the basic linear regression problem is formulated that is at the heart of many ST. Second reference is made to a framework for analyzing and understanding the statistical properties of ST, the selection of the order, as well as to a number of open problems in the understanding of important choices the user has to made. Closed-loop identification experiments are considered in the third part of section "Combined Deterministic-Stochastic ST," while the fourth part makes a brief reference to ST papers that go beyond the LTI case.

Finally we provide a brief overview on future research directions and conclude with some recommended literature for further exploration.

ST in Identification: Problems and Strategy

The LTI system to be analyzed in this chapter is given by the following state-space model:

$$x(k + 1) = Ax(k) + Bu(k) + Ke(k)$$

$$y(k) = Cx(k) + Du(k) + e(k) \qquad (1)$$

with $u(k) \in \mathbb{R}^m$ the (measurable) input, $e(k)$ a zero-mean, white-noise sequence with $E[e(k)e(k)^T] = R$, $y(k) \in \mathbb{R}^\ell$ the (measurable) output, and $x(k) \in \mathbb{R}^n$ the state vector. This model is in the so-called innovation form since the sequence $e(k)$ is the innovation signal in a Kalman filtering context.

The historical sequence of ST developments considers the following open-loop problem formulations. In the deterministic realization problem, the innovation sequence $e(k)$ is zero, and the input $u(k)$ is an impulse. The stochastic realization problem considers the case where the input $u(k)$ is zero and the given data is assumed to be samples of the covariance function of the output. The combined deterministic-stochastic identification problem considers the model (1) for generic input $u(k)$.

The general strategy of ST is to formulate an *intermediate step* in deriving the parameters of the system matrices of interest from the given data; see Fig. 1. This intermediate step makes the ST different from the parametric model identification framework that aims for a direct estimation of the parameters of the system matrices by (in general) nonlinear parameter optimization techniques. The intermediate step in ST aims to determine a matrix from the given data that *reveals* an (approximation of an) essential subspace of the unknown system. This essential subspace can be

Intermediate ST strategy

Given Data:
$\{u(k), y(k)\}_{k=1}^N$
or $\{CA^{j-1}B\}_{j=1}^N$
etc.
— Subspace Revealing Matrix — State Space Model Realization

Direct (Non–Linear) Parameter Optimization Strategy
Subspace Techniques in System Identification, Fig. 1 Schematic representation of the intermediate step of ST to derive from the given data (input–output data $\{u(k), y(k)\}$, Markov parameters $\{CA^{j-1}B\}$, etc.) a subspace revealing matrix, from which the subspace of interest is computed via, e.g., singular value decomposition and that enables the computation of the state-space model realization by solving a (convex) linear least-squares problem. The commonly used approach to directly go from the given data to a state-space realization via in general nonlinear parameter optimization methods is indicated by the arrow directly connecting the given data box to the state-space realization box

the extended observability matrix of (1) as given by the matrix $\mathcal{O}_s$:

$$\mathcal{O}_s = \begin{bmatrix} C \\ CA \\ \cdots \\ CA^{s-1} \end{bmatrix} \quad \text{for} \ \ s > n,$$

or the state sequence of a Kalman filter designed for (1). Essential for ST is that both the intermediate step to reveal the subspace of interest and the subsequent derivation of the system matrices from that subspace and the given data are done via convex optimization methods and/or linear algebra methods.

Realization Theory: The Progenitor of ST

The Deterministic Realization Problem

In the 1960s, the cited result of Kronecker inspired independently Ho and Kalman, Silverman and Youla, and Tissi to present an algorithm to construct a state-space model from a Hankel matrix of impulse response coefficients (Schutter 2000). This breakthrough gave rise to the field of *realization theory*. One key problem in realization theory that paved the way for subspace identification is the determination of a minimal realization from a finite number of samples of the impulse response of a deterministic system, assumed to have a minimal representation as in (1) for $e(k) \equiv 0$. The samples of the impulse response are called the *Markov parameters*. The minimal realization sought for is the LTI model with quadruple of system matrices $[A_T, B_T, C_T, D]$, with $A_T \in \mathbb{R}^{n \times n}$ and n minimal such that the pair (A_T, C_T) is observable, the pair (A_T, B_T) is controllable, and the transfer function $D + C_T(zI - A_T)^{-1}B_T$ equals $D + C(zI - A)^{-1}B$ with z the complex variable of the z-transform. When A is stable, the latter transfer function can be written into the matrix power series:

$$D + C(zI - A)^{-1}B = D + \sum_{j=1}^{\infty} CA^{j-1}Bz^{-j} \quad (2)$$

Following the cited result of Kronecker, the solution to the minimum realization problem is based on the construction of the (block-)Hankel matrix $H_{s,N}$ constructed from the Markov parameters $\{CA^{j-1}B\}_{j=1}^{N}$ as

$$H_{s,N} = \begin{bmatrix} CB & CAB & \cdots & CA^{N-s}B \\ \vdots & & \ddots & \vdots \\ CA^{s-1}B & CA^s B & \cdots & CA^{N-1}B \end{bmatrix} \quad (3)$$

For the deterministic realization problem, the *intermediate ST step* simply is the storage of the impulse response data into a Hankel matrix. The subsequent step is to derive from this matrix a subspace from which the system matrices can be either read-off or computed via linear least squares. How this is done is outlined next.

When the order n of the minimal realization is known and the Hankel matrix dimension parameters s, N are chosen such that

$$s > n \quad N \geq 2n - 1 \quad (4)$$

the Hankel matrix $H_{s,N}$ has **rank** n. A numerically reliable way to compute that rank is via the SVD of $H_{s,N}$. Under the assumption that the rank of $H_{s,N}$ is n, we can denote that SVD as $U_n \Sigma_n V_n^T$, with $\Sigma_n \in \mathbb{R}^{n \times n}$ positive definite and with the columns of the matrices U_n and V_n orthonormal. By the minimality of (1) (for $e(k) \equiv 0$), $H_{s,N}$ can be factored as $\mathcal{O}_s \begin{bmatrix} B \ AB \cdots A^{N-s}B \end{bmatrix} = \mathcal{O}_s \mathcal{C}_{N-s+1}$ or as $\left(U_n \Sigma_n^{\frac{1}{2}} \right)\left(\Sigma_n^{\frac{1}{2}} V_n^T \right)$, and these factors are related as

$$U_n \Sigma_n^{\frac{1}{2}} = \mathcal{O}_s T^{-1} = \mathcal{O}_{s,T} \quad \Sigma_n^{\frac{1}{2}} V_n^T = T\mathcal{C}_{N-s+1}$$
$$= \mathcal{C}_{N-s+1,T}$$

for $T \in \mathbb{R}^{n \times n}$ a nonsingular transformation. Therefore $\mathcal{O}_{s,T}$ resp. $\mathcal{C}_{N-s+1,T}$ act as the extended observability resp. controllability matrix of a similarly equivalent triplet of system matrices (A_T, B_T, C_T). This correspondence allows to read-off the system matrices C_T and B_T as the first ℓ rows of the matrix $\mathcal{O}_{s,T}$ and the first m columns of $\mathcal{C}_{N-s+1,T}$ resp. Further

the *shift-invariance* property of the extended observability resp. controllability matrices allows to find the system matrix A_T of the minimal realization. For example, consider the extended observability matrix $\mathcal{O}_s$, then the shift-invariance property states that:

$$\mathcal{O}_{s,T}(1:(s-1)\ell,:)A_T = \mathcal{O}_{s,T}(\ell+1:s\ell,:) \quad (5)$$

where the notation $M(u : v, :)$ indicates the submatrix of M from rows u to rows v. The shift-invariance property delivers a set of linear equations from which the system matrix A_T can be computed via the solution of a **linear** least-squares problem when $s > n$.

Finding the dimension parameters s (and N) of the Hankel matrix $H_{s,N}$ is a nontrivial problem in general. When only the Markov parameters are given and the knowledge that they stem from a finite-order state-space model, a possible sequential strategy is to select s and N equal to the upperbounds in (4) for presumed orders n and $n + 1$, respectively. When the rank of the Hankel matrices for these two selections of s (and N) is identical, the right dimensioning of the Hankel matrix $H_{s,N}$ is found. Otherwise the presumed order is increased by one.

The Stochastic Realization Problem

The output-only identification problem aims at determining a mathematical model from a measured multivariate time series $\{y(k)\}_{k=1}^N$ with $y(k) \in \mathbb{R}^\ell$. Such a model can be then used for predicting future values of the (output) data from past values.

In the vein of the revival of the work of Kronecker on realizing dynamical systems from its impulse response, Faure and a number of contemporaries like Akaike and Aoki made pioneering contributions to extend this methodology to stochastic processes (Van Overschee and De Moor 1993). These extensions are known as solutions to the stochastic realization problem.

This problem is formulated for $y(k)$ to be a Markovian stochastic process. Reusing the notation in (1) $y(k)$ is assumed to be generated by (1) with the input $u(k) \equiv 0$. The A matrix in (1) is again assumed to be stable. The given data in

the early formulations of the stochastic realization problem was the samples of the covariance function

$$R_y(j) = E[y(k)y(k-j)^T]$$

These samples define the strictly positive real spectral density function of $y(k)$:

$$\Phi_y(z) = \sum_{j=-\infty}^{\infty} R_y(j)z^{-j} > 0 \quad (6)$$

Given the samples of the covariance function $R_y(j)$, the stochastic realization problem was to find an innovation model representation of the form

$$\hat{x}(k + 1) = A_T\hat{x}(k) + K_Te'(k)$$
$$\tilde{y}(k) = C_T\hat{x}(k) + e'(k) \quad (7)$$

with $e'(k)$ a zero-mean, white-noise input with covariance matrix R_e, the pair (A_T, C_T) observable, and A_T stable, such that the spectral density functions $\Phi_y(z)$ and $\Phi_{\tilde{y}}(z)$ are equal.

The partial similarity between this problem and the minimal realization problem becomes clear when expressing the covariance function samples $R_y(j)$ in terms of the system matrices in (1)–for $u(k) \equiv 0$ as

$$R_y(j) = CA^{j-1}G \quad \text{for} \quad j \neq 0 \quad (8)$$

with the matrices G and $R_y(0)$ derived from the following covariance expressions:

$$E[x(k)x(k)^T] = \Sigma_x : \Sigma_x$$
$$= A\Sigma_x A^T + KRK^T \quad (9)$$
$$E[x(k+1)y(k)^T] = G : G$$
$$= A\Sigma_x C^T + KR \quad (10)$$
$$E[y(k)y(k)^T] = R_y(0) : R_y(0)$$
$$= C\Sigma_x C^T + R \quad (11)$$

Since the spectral density has a two-sided series expansion, there is a so-called forward stochastic

realization problem (considering $R_y(j)$ for $j \geq 0$ only) and a backward version. Here we only treat the forward one. Drawing the parallel between the samples of the covariance function $R_y(j)$, as given in (6)–(8) and the Markov parameters in (2), we can use the deterministic tools from realization theory to find a minimal realization (A_T, C_T, G_T).

The *intermediate ST step* in the stochastic realization problem is the construction of a Hankel matrix similar to the matrix $H_{s,N}$ as in the deterministic realization problem but now from the samples of the covariance function $R_y(j)$ in (8).

With the triplet (A_T, C_T, G_T) determined, the innovation model (7) is classically completed via the solution of a Riccati equation in the unknown Σ_x. This Riccati equation results by noting that $R > 0$, and therefore, KRK^T can be written as $KR(R)^{-1}R^T K^T$. This reduces the expression for Σ_x in (9) with the help of (10) and (1) as

$$
\begin{aligned}
\Sigma_x = A\Sigma_x A^T + (G - A\Sigma_x C^T)(R_y(0) \\
- C\Sigma_x C^T)^{-1}(G - A\Sigma_x C^T)^T
\end{aligned} \quad (12)
$$

By replacing the triplet (A, C, G) with the found minimal realization (A_T, C_T, G_T) in this Riccati equation, its solution $\Sigma_{x,T}$ enables in the end to define the missing quantities as

$$
\begin{aligned}
R_e &= R_y(0) - C_T \Sigma_{x,T} C_T^T \\
K_T &= (G_T - A_T \Sigma_{x,T} C_T^T) R_e^{-1}
\end{aligned} \quad (13)
$$

By the positive realness of $\Phi_y(z)$ and the similar equivalence between the triplets (A_T, C_T, G_T) and (A, C, G), the solution $\Sigma_{x,T}$ is positive definite.

A persistent problem in solving the stochastic realization problem has existed for a long time when using approximate values of the samples $R_y(j)$. This problem is that the estimated power spectrum based on estimates of the triplet (A_T, C_T, G_T) is *no longer positive real*.

An approximate solution overcoming the problem of the loss of positive realness of the estimated power spectrum was provided in the vein of the ST developed in the early 1990s as discussed in the next section.

Combined Deterministic-Stochastic ST

Identification of LTI MIMO Systems in Open Loop

Since the golden 1960s and 1970s of the twentieth century, many attempts have been made to make the insights from deterministic and stochastic realization theory useful for system identification. To mention a few, there are attempts to use the solutions to the deterministic realization problem with measured or estimated impulse response data. One such method is known under the name of the eigensystem realization algorithm (ERA) (Juang and Pappa 1985) and has been used for modal analysis of flexible structures, like bridges, space structures, etc. Although these methods tend to work well in practice for these resonant structures that vibrate (strongly), they did not work well for other type of systems and an input different from an impulse. Extensions to the stochastic realization problem considered the use of finite sample average estimates of the covariance function as an attempt to make the method work with finite data length sequences. As indicated in section "The Stochastic Realization Problem," these approximations of the covariance function tended to violate the positive realness property of the underlying power spectrum.

In the early 1990s of the twentieth century, new breakthroughs were made working directly with the input–output data of an assumed LTI system without the need to first compute the Markov parameters or estimating the samples of covariance functions. Pioneers that contributed to these breakthroughs were Van Overschee and De Moor, introducing the N4SID approach (Van Overschee and De Moor 1994); Verhaegen, introducing the MOESP approach (Verhaegen 1994); and Larimore, presenting ST in the framework of canonical variate analysis (CVA) (Larimore 1990).

These three pioneering contributions considered the identification of the state-space model

S

(1) from the input–output data $\{u(k), y(k)\}_{k=1}^{N}$ recorded in *open loop*. The pair (A, C) was assumed to be observable, and the pair (A, KR) controllable. The innovation noise covariance matrix R was assumed to be positive definite.

The formulation of the *intermediate ST step* from which these three pioneering contributions can be derived (by weighting the result of Theorem 1) and that is at the heart of many more variants is summarized in Theorem 1. This theorem requires two preparations: first the storage of the input and output sequences into (block-) Hankel matrices and relating these Hankel matrices via the model parameters and second to make three observations about the model (1) when presented in the prediction form. This form is obtained by replacing $x(k)$ by $\hat{x}(k)$ and $e(k)$ by $y(k) - C\hat{x}(k) - Du(k)$ and is given by

$$\hat{x}(k+1) = (A - KC)\hat{x}(k)$$
$$+ (B - KD)u(k) + Ky(k)$$
$$y(k) = C\hat{x}(k) + Du(k) + e(k) \quad (14)$$

To compact the notation we make the following substitutions: $\mathcal{A} = (A - KC)$ and $\mathcal{B} = [(B - KD) \ K]$.

Let the Hankel matrix with the "future" part $\{y(k)\}_{k=p+1}^{N}$ be defined as

$$Y_f = \begin{bmatrix} y(p+1) & y(p+2) & \cdots & y(N-f+1) \\ y(p+2) & & & \\ \vdots & & \ddots & \\ y(p+f) & & \cdots & y(N) \end{bmatrix}$$
$$(15)$$

for the dimensioning parameters p and f selected such that

$$p \geq f > n$$

In a similar way we define the Hankel matrices U_f and E_f from the input $u(k)$ and the innovation $e(k)$, respectively. Then with the definition of the (block-)Toeplitz matrix T_u from the quadruple of system matrices (A, B, C, D) as

$$T_u = \begin{bmatrix} D & 0 & \cdots & 0 \\ CB & D & & 0 \\ CAB & CB & & 0 \\ & & \ddots & \\ CA^{f-1}B & CA^{f-2}B & \cdots & D \end{bmatrix}$$

and similarly the definition of the Toeplitz matrix T_e from the quadruple of system matrices (A, K, C, I), we can relate the data Hankel matrices Y_f and U_f as

$$Y_f = O_f \left[\hat{x}(p+1) \cdots \hat{x}(N-f+1) \right]$$
$$+ T_u U_f + T_e E_f$$
$$= O_f \hat{X}_f + T_u U_f + T_e E_f \quad (16)$$

Based on the prediction form (14), **3**, key observations are made to support the rational of the intermediate step summarized in Theorem 1:

O1: The standard assumption that the transfer function from $e(k)$ to $y(k)$ is minimum phase leads to the fact that matrix $\mathcal{A}$ is stable. Therefore, there exists a finite integer p such that
$$\mathcal{A}^p \approx 0$$

O2: The state-pace model of (14) has inputs $u(k)$ and $y(k)$. Grouping both together into the new vector $z(k) = \begin{bmatrix} u(k) \\ y(k) \end{bmatrix}$ enables to express the state $\hat{x}(k+p)$ as

$$\hat{x}(k+p) = \mathcal{A}^p \hat{x}(k) + \sum_{j=1}^{p} \mathcal{A}^{j-1} \mathcal{B} z(k+p-j)$$

for $k \geq 1$. With the assumption that $\mathcal{A}^p \approx 0$ and the definition of the input-output data vector sequence $Z(k) = \left[z(k)^T \cdots z(k+p-1)^T \right]^T$, we have the following approximation of the state:

$$\hat{x}(k+p) \approx \left[\mathcal{A}^{p-1}\mathcal{B} \cdots \mathcal{B} \right] Z(k) = \mathcal{L}^z Z(k)$$

As such the state sequence $\hat{X}_f$ in (16) can be approximated by

$$\mathcal{L}^z Z_p = \mathcal{L}^z \left[Z(1) Z(2) \cdots Z(N-f-p+1) \right].$$

O3: The (approximate) knowledge of the row space of the state sequence in $\hat{X}_f$ makes that the unknown system matrices (A, B, C, D, K) appear (approximately) linearly in the model (14).

The intermediate ST step to retrieve a matrix with relevant subspaces is summarized in the following theorem taken from Peternell et al. (1996).

Theorem 1 (Peternell et al. 1996) *Consider the model* (1) *with all stochastic processes assumed to be ergodic and with the input* $u(k)$ *to be statistically uncorrelated from the innovation* $e(\ell)$ *for all* k, ℓ. *Consider the following least-squares problem:*

$$\begin{bmatrix} \hat{L}_N^u & \hat{L}_N^z \end{bmatrix} = \arg \min_{L^u, L^z} \|Y_f - \begin{bmatrix} L^u & L^z \end{bmatrix} \begin{bmatrix} U_f \\ Z_p \end{bmatrix}\|_F^2 \tag{17}$$

with $\|.\|_F^2$ *denoting the Frobenius norm of a matrix, then*

$$\lim_{N \to \infty} \hat{L}_N^z = \mathcal{O}_f \mathcal{L}_z + \mathcal{O}_f \mathcal{A}^p \Delta_z$$

with Δ_z *a bounded matrix.*

The theorem delivers the matrix $\hat{L}_N^z$ via the solution of a convex linear least-squares problem that has asymptotically (in the number of measurements N) the extended observability matrix $\mathcal{O}_f$ as its column space and that has asymptotically (in the number of measurements as well as in the dimension parameter p) the matrix $\mathcal{L}^z$ as its row space. Based on the expression of the state sequence $\hat{X}_f$ given in the observation O2 above, the estimate of the row space of $\mathcal{L}^z$ delivers an estimate of the row space of the state sequence $\mathcal{X}_f$. The observation O3 then shows that this intermediate step allows to derive an estimate of the system matrices $[A, B, C, D, K]$ (up to a similarity transformation) via a linear least-squares problem.

Towards Understanding the Statistical Properties

Many ST variants for system identification using data recorded in open loop have been developed since the early 1990s of the twentieth century. These variants mainly differ in the use of weighting matrices $\mathcal{W}_\ell$ and $\mathcal{W}_r$ in the product $\mathcal{W}_\ell \hat{L}_N^z \mathcal{W}_r$ prior to computing the subspaces of interest. The effect on the accuracy and the statistical properties of the estimated model by these weighting matrices is yet not fully understood as is that of the dimensioning parameters p and f in the definition of the data Hankel matrices Y_f, U_f, Z_p. Only for very specific restrictions results have been achieved. For example, in Bauer and Ljung (2002), it has been shown that when the input $u(k)$ in (1) is either non-present or zero-mean white noise, as well as when the system order n of the underlying system to be known and letting in addition to the dimension parameter p and the number of data points N the dimension parameter f go to infinity, that the weighting matrices selected to represent the CVA approach (Larimore 1990) yield an optimal *minimum variance* estimate. A framework for analyzing the statistical properties like consistency and asymptotic distribution of the estimates determined by the class of STs that were discovered in the 1990s is given in Bauer (2005).

The minimum variance property of the estimates by the CVA approach (Larimore 1990) is theoretically not yet proven for more generic and practically relevant experimental conditions. For these cases, the choices of the different weighting matrices, the dimensioning parameters f, p, as well as selecting the system order are often diverted to user. Despite this fact, practical evidence has shown that STs are able to accurately identify state-space models for LTI MIMO systems under industrially realistic circumstances. As such they are by now accepted and widely used as a common engineering tool in various areas, such as model-based control, fault diagnostics, etc. Further they generally provide excellent initial estimates to the nonlinear parametric optimization methods in prediction error or maximum likelihood estimation methods.

Identification of LTI MIMO Systems in Closed Loop

The least-squares problem (17) in Theorem 1 leads to biased estimates when using

input-output data that is recorded in a closed-loop identification experiment. This is because of the correlation between the measurable input and the innovation sequence. A number of solutions have been developed to overcome this problem. We refer to the paper van der Veen et al. (2013) for an overview of a number of these rescues. A simple and performant rescue is described here based on the work in Chiuso (2010). The *intermediate ST step* in order to avoid biased estimates is to estimate a high-order vector autoregressive models with exogenous inputs, a so-called VARX model:

$$\min_{\Theta} \sum_{k=1}^{N-p} \| y(k + p) - \Theta Z(k) - Du(k + p)\|_2^2 \tag{18}$$

Using the result on the approximation of the state vector $\hat{x}(k + p)$ in observation O2, it can be shown that the solution $\hat{\Theta}$ of (18) is an approximation of the parameter vector:

$$\hat{\Theta} = \left[\widehat{C\mathcal{A}^{p-1}\mathcal{B}} \cdots \widehat{C\mathcal{B}} \right]$$

Then using this solution $\hat{\Theta}$ and O1 above leads to the following "subspace revealing matrix" (cf. Fig. 1):

$$\begin{bmatrix} \widehat{C\mathcal{A}^{p-1}\mathcal{B}} & \widehat{C\mathcal{A}^{p-2}\mathcal{B}} & \cdots & \widehat{C\mathcal{A}^{p-f}\mathcal{B}} & \cdots & \widehat{C\mathcal{B}} \\ 0 & \widehat{C\mathcal{A}^{p-1}\mathcal{B}} & \widehat{C\mathcal{A}^{p-f+1}\mathcal{B}} & \cdots & \widehat{C\mathcal{A}\mathcal{B}} \\ \vdots & & \ddots & & \\ 0 & 0 & \cdots & \widehat{C\mathcal{A}^{p-1}\mathcal{B}} & \cdots & \widehat{C\mathcal{A}^{f-1}\mathcal{B}} \end{bmatrix} \tag{19}$$

As in the open-loop case of section "Identification of LTI MIMO Systems in Open Loop," column and row weighting matrices as well as changing the size of the subspace revealing matrix (19) can be used to influence the accuracy of the estimates (Chiuso 2010). The subspace of interest of this weighted subspace revealing matrix is its row space that is an approximation of that of the state sequence $\hat{X}_f$ as in (16), now extended to make the size compatible to the weighted version of (19). Similarly as in the open-loop case, knowledge of this subspace turns the estimation of the system matrices $[A, B, C, D, K]$ (up to a similarity transformation) into a linear least-squares problem. The statistical asymptotic properties of this closed-loop ST and the treatment of the dimensioning parameters have also been studied in Chiuso (2010). Here, the result is proven that the asymptotic variance of any system invariant of the model estimated via the above closed-loop ST is a nonincreasing function of the dimensioning parameter f when the input $u(k)$ to the plant is generated by an LQG controller with a white-noise reference input.

Beyond LTI Systems

The summarized discrete-time ST methodology has been extended in various ways. A number of important extensions including representative papers are towards continuous-time systems (van der Veen et al. 2013), using frequency-domain data (Cauberghe 2006) or for different classes of nonlinear systems, like block-oriented Wiener and/or Hammerstein and linear parameter-varying systems (van Wingerden and Verhaegen 2009). ST for linear time-varying systems with changing dimension of the state vector is treated in Verhaegen and Yu (1995), and finally we mention the developments to make ST recursive (van der Veen et al. 2013).

Summary and Future Directions

Subspace techniques aim at simplifying the system identification cycle and make it more user-friendly. Still a number of challenges persist in improving on this general goal. A critical one is the "optimal" selection of the weighting matrices and the dimensioning parameters p and f of the subspace revealing matrix. Optimality here can be expressed, e.g., by the minimality of the variance of the estimates but could also be viewed more generally in relationship with the use of the model, e.g., in terms of the performance of a model-based closed-loop design. A profound theoretical framework is necessary to fully automate the selection of the weighting matrices and dimensioning and order indices. This would substantially contribute to fully automated identification procedures for doing system identification (for linear systems).

A second challenge is to better integrate ST with robust controller design. This requires the assessment of the model quality and the selection of an optimal input. Particular to the integration of ST to control design is the striking similarity of data equations used in ST and model predictive control. The challenge is to further exploit this similarity to develop data-driven model predictive control methodologies that are robust w.r.t. the identified model uncertainty.

One interesting development in ST is the use of regularization via the nuclear norm in order to improve the model order selection with respect to, e.g., SVD-based ST in Liu and Vandenberghe (2010).

A final challenge is to extend ST for LTI systems to other classes of dynamic systems, such as nonlinear, hybrid, and large-scale systems.

Recommended Reading

The recommended readings for further study are the books that appeared on the topic of subspace identification. In the books Verhaegen and Verdult (2007) and Katayama (2005), the topic of subspace identification is treated in a wider context for classroom teaching at the MSc level since more elaborate topics relevant in the understanding of ST are treated, such as key results from linear algebra, linear least squares, and Kalman filtering. The book Van Overschee and De Moor (1996) is focused on subspace identification only and also emphasizes the success of ST on various applications. All these books provide access to numerical implementations for getting hands-on experience with the methods. The integration of subspace methods with other identification approaches is done in the toolbox (Ljung 2007).

There also exist a number of overview articles. An overview of the early developments of ST since the 1990s of the twentieth century is given in Viberg (1995). Here also the link between ST for identifying dynamical systems and the signal processing application of direction-of-arrival problems was clearly made. A more recent overview article is van der Veen et al. (2013). In this article also reference is made to the statistical analysis and closed-loop application of ST.

Many papers have appeared reporting successful application of subspace methods in practical applications. We refer to the book Van Overschee and De Moor (1996) and the overview paper van der Veen et al. (2013).

Supervisory Control of Discrete-Event Systems

W.M. Wonham
Department of Electrical & Computer Engineering, University of Toronto, Toronto, ON, Canada

Abstract

We introduce background and base model for supervisory control of discrete-event systems, followed by discussion of optimal controller existence, a small example, and summary of control under partial observations. Control architecture and symbolic computation are noted as approaches to manage state space explosion.

Keywords

Asynchronous; Control architectures; Controllability; Discrete; Dynamics; Finite automata; Observability; Optimality; Regular languages; Symbolic computation

Introduction

Discrete-event (dynamic) systems (DES or DEDS) constitute a relatively new area of control science and engineering, which has taken its place in the mainstream of control research. Recently, DES have been combined with continuous systems in an area called hybrid systems.

Problems and methods for DES have been investigated for some time, although not necessarily with a "control" flavor. The parent domains can be identified as operations research and software engineering.

Operations research deals with systems of interconnected stores and servers which operate on processed items. For instance, manufacturing systems employ queues, buffers, and bins (which store workpieces). These are served by machines, robots, and automatic guided vehicles (AGVs), which process workpieces. The main problems are to measure quantitative performance and establish trade-offs, for instance flow vs. cost, and to optimize design parameters such as buffer size and maintenance frequency.

The relevant areas of software engineering include operating systems control, concurrent computing, and real-time (embedded or reactive) systems, with focus on synchronization algorithms that enforce mutual exclusion and resource sharing in the presence of concurrency, as in the classical problems of Readers & Writers and Dining Philosophers. The main objectives are (i) to guarantee safety ("Nothing bad will ever happen"), as in mutual exclusion and deadlock prevention, and (ii) to guarantee liveness ("Something good will happen eventually"), for instance, successful computational termination and eventual access to a desired resource.

DES from a Control Viewpoint

With these domains in mind, we consider DES from a control viewpoint. In general, control deals with dynamic systems, defined as entities consisting of an internal state space, together with a state-evolution or transition structure, and equipped (for control purposes) with both an input mechanism for actuation and an output channel for observation and feedback. The objective of control is to bring together information and dynamics in some purposeful combination: the interplay between observation and control or decision-making is fundamental.

In this framework, a DES is a dynamic system that is discrete, in time and usually in state

space; is asynchronous or event driven, that is driven by events or instantaneous happenings in time (which may or may not include the tick of a clock); and is nondeterministic, namely, embodies internal chance or other unmodeled mechanisms of choice which govern its state transitions. With a manufacturing system, for example, the dynamic state might include the status of machines (idle, working, down, under maintenance or repair), the contents of queues and buffers, and the locations and loads of robots and AGVs, while transitions (discrete events) occur when queues and buffers are incremented or decremented, robots load or unload, and machines start work, finish work, or break down (the "choice" between finishing work successfully and breaking down, being thus nondeterministic). In this example and many others, the objectives of design and analysis include logical correctness in the presence of concurrency and timing constraints, and quantitative performance such as rates of production, all of which depend crucially on feedback control synthesis and optimization. To this end the models will tend to be DES or hybrid systems. Nevertheless one finds the continuing relevance of standard control-theoretic concepts like feedback, stability, controllability, and observability, along with their roles in large-system architectures embodying hierarchical, decentralized, and distributed functional organization.

Here we focus on models and problems from which explicit constraints of timing are absent and which can be considered in a framework of finite-state machines and the corresponding regular languages. While the theory has been generalized to more flexible and technically advanced settings, our restricted framework is already rich enough to support numerous applications and remains challenging for large systems of industrial size.
Base Model for Control of DES

The formal structure of a DES to be controlled will resemble the simple "machine" called **MACH** shown in Fig. 1. The state set of **MACH**

is $Q = \{I, W, D\}$, interpreted as Idle, Working, or Broken Down. **MACH** is initialized at state $q_o = I$, denoted by an entering arrow without source. The transition structure is displayed in Fig. 1 as a transition diagram, whose nodes are the states $q \in Q$ and edges are the transitions, each labeled with a symbol σ in the alphabet Σ, here $\{w, c, b, r\}$. If a transition (labeled) σ is an edge from q to q', then "the event σ can occur at state q." Transitions (or events) are interpreted as instantaneous in time, while states are thought of as locations where **MACH** is able to reside for some indeterminate time interval. The occurrence of w means "**MACH** enters the Working state from Idle" and similarly for c, b, r. These transitions determine the state-transition function of **MACH**, denoted by $\delta : Q \times \Sigma \to Q$. Thus $\delta(I, w) = W$, $\delta(W, b) = D$, and so on. Notice that δ is a partial function, defined at each state $q \in Q$ for only a subset of event (labels) in Σ. To denote that $\delta(q, \sigma)$ is defined at state $q \in Q$ for the event $\sigma \in \Sigma$, we write $\delta(q, \sigma)!$. The function δ can be extended in a standard way to $\delta : Q \times \Sigma^* \to Q$, where Σ^* is the set of all finite strings of elements of Σ, including the empty string ϵ. Thus $\delta(q, \epsilon) := q$ and inductively if $q' := \delta(q, s)!$, then

$$\delta(q, s.\sigma) := \delta(\delta(q, s), \sigma) := \delta(q', \sigma)$$

whenever $\delta(q', \sigma)!$. Graphically the strings $s = \sigma_1 \ldots \sigma_k \in \Sigma^*$ for which $\delta(q, s)!$ are precisely those for which there exists a path in the transition diagram starting from q and having successive edges labeled $\sigma_1, \ldots, \sigma_k$.

We call any subset of Σ^* (i.e., any set of strings of elements from Σ) a language over Σ and accordingly speak of sublanguages of a language over Σ.

For **MACH**, the execution of a production cycle, namely the event sequence (or string) $w.c$, or a work-breakdown-repair cycle, the string $w.b.r$, can be considered successful, and the corresponding string is said to be marked. States which are entered by marked strings are marked states and identified in a transition diagram by an outgoing arrow with no target. In Fig. 1, the only marked state happens to be the initial state, which is thus shown with a double arrow; in general there could be several marked states, which may or may not include the initial state. The marked states comprise a subset $Q_m \subseteq Q$, which may be empty (at one extreme) or equal to Q (at the other). The case $Q_m = Q$ (all states marked) would imply that every string of events is considered as significant or successful as any other, while the case $Q_m = \emptyset$ (no state marked, so there are no successful strings) plays a technical role in computation.

In general a generator is a tuple $\mathbf{G} = (Q, \Sigma, \delta, q_o, Q_m)$ usually interpreted physically as for **MACH** above, but mathematically consisting merely of the finite-state set Q, finite alphabet Σ, marked subset $Q_m \subseteq Q$, with initial state $q_o \in Q$, and (partial) transition function $\delta : Q \times \Sigma \to Q$. Additionally we bring in the closed behavior $L(\mathbf{G})$ of $\mathbf{G}$, defined as all the strings of Σ^* which $\mathbf{G}$ can generate starting from the initial state, in the sense

$$L(\mathbf{G}) := \{s \in \Sigma^* \mid \delta(q_o, s)!\}.$$

Of central importance also is the marked behavior of $\mathbf{G}$, namely, the sublanguage of $L(\mathbf{G})$ given by

$$L_m(\mathbf{G}) := \{s \in L(\mathbf{G}) \mid \delta(q_o, s) \in Q_m\}.$$

We need several definitions. A string s' is a prefix of a string $s \in \Sigma^*$, written $s' \leq s$, if s' can be extended to s, namely, there exists a string w in Σ^* such that $s'.w = s$. The closure of a language $M \subseteq \Sigma^*$ is the language $\overline{M}$ consisting of all prefixes of strings in M:

$$\overline{M} := \{s' \in \Sigma^* \mid s' \leq s \text{ for some } s \text{ in } M\}$$

Supervisory Control of Discrete-Event Systems, Fig. 1
MACH

A language N over Σ is (prefix-)closed if it contains all its prefixes, namely, $N = \overline{N}$. In this notation $\mathbf{G}$ is said to be nonblocking if $L(\mathbf{G}) = \overline{L_m(\mathbf{G})}$, namely, any (generated) string in $L(\mathbf{G})$ is a prefix of, and so can be extended to, a marked string of $\mathbf{G}$.

The semantics of $\mathbf{G}$ (its mathematical meaning) is simply the pair of languages $L_m(\mathbf{G})$, $L(\mathbf{G})$. In general the latter may be infinite subsets of Σ^*, while $\mathbf{G}$ itself is a finite object, considered to represent an algorithm for the generation of its behaviors. Unless $\mathbf{G}$ is trivial (has empty state set), it is always true that $\epsilon \in L(\mathbf{G})$.

Transition labeling of $\mathbf{G}$ is deterministic: at every q, at most one transition is defined for each given event σ, namely,

$$\delta(q, \sigma) = q' \ \& \ \delta(q, \sigma) = q'' \text{ implies } q' = q''.$$

It is quite acceptable, however, that at distinct states q and r, both $\delta(q, \sigma)!$ and $\delta(r, \sigma)!$ (where these evaluations are usually not equal).

To formulate a control problem for $\mathbf{G}$, we first adjoin a control technology or mechanism by which $\mathbf{G}$ may be actuated to affect its temporal behavior, namely, determine the strings it is permitted to generate. To this end we assume that a subset of events $\Sigma_c \subseteq \Sigma$, called the controllable events, are capable of being enabled or disabled by an external controller. Think of a traffic light being turned green or red to allow or prohibit passage (vehicle transition) through an intersection. The complementary event subset $\Sigma_u := \Sigma - \Sigma_c$ is uncontrollable; events $\sigma \in \Sigma_u$ cannot be externally disabled but may be considered permanently enabled. For $\mathbf{G} = \mathbf{MACH}$ one might reasonably assume $\Sigma_c = \{w, r\}$, $\Sigma_u = \{c, b\}$. At a given state q of $\mathbf{G}$, it will be true in general that $\delta(q, \sigma)!$ both for some (controllable) events $\sigma \in \Sigma_c$ and for some (uncontrollable) events $\sigma \in \Sigma_u$. Among the $\sigma \in \Sigma_c$, at a given time, some may be externally enabled and others disabled. So, $\mathbf{G}$ will nondeterministically choose its next generated event from the subset

$$\{\sigma \in \Sigma_u \mid \delta(q, \sigma)!\} \cup \{\sigma \in \Sigma_c \mid \delta(q, \sigma)! \ \&$$
$$\sigma \text{ is externally enabled}\} \tag{1}$$

We formalize external enablement by a supervisory control function $V : L(\mathbf{G}) \rightarrow Pwr(\Sigma)$, where $Pwr(.)$ stands for power set. For $s \in L(\mathbf{G})$, the evaluation $V(s)$ is defined to be the event subset

$$V(s) := \Sigma_u \cup \{\sigma \in \Sigma_c \mid \sigma \text{ is externally enabled}$$
$$\text{following } s\} \tag{2}$$

In other words, the set (1) is expressible as

$$V(s) \cap \{\sigma \in \Sigma \mid s.\sigma \in L(\mathbf{G})\} \tag{3}$$

namely, the subset of events that, immediately following the generation of s by $\mathbf{G}$, are either enabled by default (executable events in Σ_u) or else by the external controller's decision (a subset of executable events in Σ_c).

It is now easy to visualize how the generating action of $\mathbf{G}$ is restricted by the action of $V(.)$. Initially (having generated the empty string) $\mathbf{G}$ chooses $\sigma_1 \in V(\epsilon)$. Proceeding inductively, after $\mathbf{G}$ has generated $s = \sigma_1.\sigma_2 \ldots \sigma_k \in L(\mathbf{G})$, s is fed back to the controller, which evaluates $V(s)$ according to (2), announcing the result to $\mathbf{G}$, which then chooses σ_{k+1} in (3), and the process repeats. Of course the process would terminate any time the set (3) happened to become empty (although it need not). In any case, we denote the subset of $L(\mathbf{G})$ so determined as $L(V/\mathbf{G})$, called the closed behavior of $V/\mathbf{G}$, where the latter symbol (formally undefined) stands for $\mathbf{G}$ under the supervision of V. It is clear that supervision is a feedback process (Fig. 2), inasmuch as the choice of σ_{k+1} in (3) is not, in general, known in advance, hence must be executed before the succeeding evaluation $V(s.\sigma_{k+1})$ can allow the generating process to continue. With the closed behavior of $V/\mathbf{G}$ now determined, we define the marked behavior

$$L_m(V/\mathbf{G}) := L(V/\mathbf{G}) \cap L_m(\mathbf{G}) \tag{4}$$

namely, those marked strings of $\mathbf{G}$ that survive under supervision by V. Thus supervisory control is nonblocking if $L(V/\mathbf{G}) = \overline{L_m(V/\mathbf{G})}$.

Feedback loop $V/\mathbf{G}$

Existence of Controls for DES: Controllability

Of fundamental interest is the question: what sublanguages of $L(\mathbf{G})$ qualify as a language $L(V/\mathbf{G})$ for some choice of supervisory control function V? In other words, what is the scope of controlled behavior(s) for a given $\mathbf{G}$? So far we know that $L(V/\mathbf{G})$ is a sublanguage of $L(\mathbf{G})$, but it is not usually the case that an arbitrary sublanguage would qualify. For instance, the empty string language $\{\epsilon\} \neq L(V/\mathbf{G})$ for any V as in (2) above, in case $\delta(q_o, \sigma)!$ for some σ in Σ_u, for such σ cannot be disabled.

Assume $\mathbf{G}$ is equipped with the technology of controllable events, hence uncontrollable events $\Sigma_u \subseteq \Sigma$. We make the basic definition: the language $K \subseteq \Sigma^*$ is controllable (with respect to $\mathbf{G}$) provided

For all $s \in \overline{K}$ and for all $\sigma \in \Sigma_u$,

whenever $s.\sigma \in L(\mathbf{G})$ then $s.\sigma \in \overline{K}$.   (5)

Informally, a string s can never exit from $\overline{K}$ as the result of the execution by $\mathbf{G}$ of an uncontrollable event: $\overline{K}$ is invariant under the uncontrollable flow. In terms of $\mathbf{G} = \mathbf{MACH}$, above, the languages $\{\epsilon\}, \{wb, wc\}$ are controllable, but $\{w\}, \{w, wcw\}$ are not. For instance, $H := \{w, wcw\}$ has closure $\overline{H} = \{\epsilon, w, wc, wcw\}$, which contains the string $s := w$, but $sb = wb$ can be executed in $\mathbf{MACH}$, b is uncontrollable, and sb has exited from $\overline{H}$. It is logically trivial from (5) that the empty language $\emptyset$ (with no strings whatever) is controllable.

We can now answer the fundamental question posed above.

Given a nonempty sublanguage $K \subseteq L(\mathbf{G})$,

there exists a supervisory control function V

                               (6)

such that $\overline{K} = L(V/\mathbf{G})$, if and only if

K is controllable.

This result exhibits the $L(V/\mathbf{G})$ property in a structured way; furthermore, both the containment $K \subseteq L(\mathbf{G})$ and the controllability property (5) (or its absence) can be effectively (algorithmically) decided in case K itself is the closed or marked behavior of some given DES over Σ.

A key fact easily provable from (5) is that the family of all controllable languages (with respect to a fixed $\mathbf{G}$) is algebraically closed under union, namely,

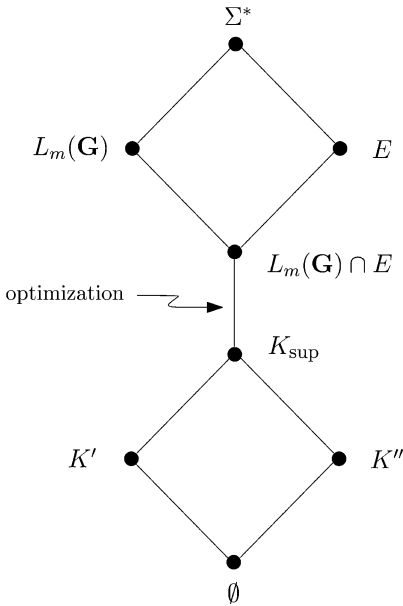
If K_1 and K_2 are controllable languages,

then so is $K_1 \cup K_2$.   (7)

In fact (7) can be extended to an arbitrary finite or infinite union of controllable languages.

Given $\mathbf{G}$ as above, considered as the plant to be controlled, suppose a new (regular) language E is specified, as the maximal set of strings that we are prepared to tolerate for generation by $\mathbf{G}$; for instance, E could be considered the legal language for $\mathbf{G}$ (irrespective of what $\mathbf{G}$ is potentially capable of generating, namely, $L(\mathbf{G})$). Let us confine attention to the sublanguage of E that contains only marked strings of $\mathbf{G}$, namely, $E \cap L_m(\mathbf{G})$. We now bring in the family $\mathcal{C}(E \cap L_m(\mathbf{G}))$ of all controllable sublanguages of $E \cap L_m(\mathbf{G})$ (including the empty language). From (7) and its infinite extension, there follows the existence of the controllable language

$$K_{\sup} := \cup\{K \mid K \in \mathcal{C}(E \cap L_m(\mathbf{G}))\} \quad (8)$$

We have $K_{\sup} \subseteq E \cap L_m(\mathbf{G})$, and clearly if K' is controllable and $K' \subseteq E \cap L_m(\mathbf{G})$, then $K' \subseteq K_{\sup}$. $K_{\sup}$ is therefore the supremal (largest) controllable sublanguage of $E \cap L_m(\mathbf{G})$. Furthermore, if $K_{\sup}$ is nonempty, then by (6) there exists a supervisory control V such that


Supervisory Control of Discrete-Event Systems, Fig. 3
Hasse diagram

Supervisory Control of Discrete-Event Systems, Fig. 4
Implementation of $V/\mathbf{G}$

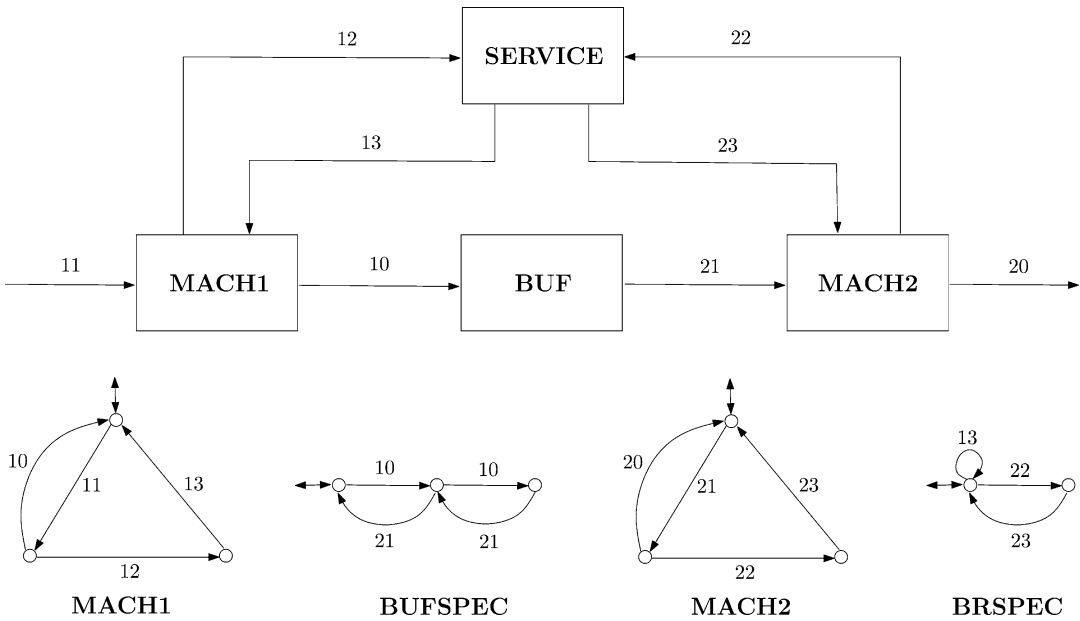
step of the process. In this way the feedback control process is inductively well defined. The computational complexity of this design (cf. (8)) is $O(|\mathbf{E}|^2 \cdot |\mathbf{G}|^2)$ where $\mathbf{E}$ is a DES with $L_m(\mathbf{E}) = E$ and $|\cdot|$ denotes state size. The controller state size is $|\mathbf{KSUP}| \leq |\mathbf{E}| \cdot |\mathbf{G}|$, the product bound being of typical order.

$K_{\text{sup}} = L(V/\mathbf{G})$; in this sense V is optimal (maximally permissive), allowing the generation by $\mathbf{G}$ of the largest possible set of marked strings that the designer considers legal. We have thus established abstractly the existence and uniqueness of an optimal control for given $\mathbf{G}$ and E. This simple conceptual picture is displayed (Fig. 3) as a Hasse diagram, in which nodes represent sublanguages of Σ^* and rising lines (edges) the relation of sublanguage containment.

In a Hasse diagram it could be that K_{sup} collapses to the empty language $\emptyset$. This means that there is no supervisory control for the problem considered, either because the specifications are too severe and the problem is over-constrained or because the control technology is inadequate (more events need to be controllable).

Under the finite-state assumption, K_{sup} is effectively representable by a DES **KSUP**, which may serve as the optimal feedback controller, as displayed in Fig. 4. Here a string s generated by $\mathbf{G}$ drives **KSUP**; at each state of **KSUP**, the events defined in its transition structure are exactly those available to $\mathbf{G}$ for nondeterministic execution (in its corresponding state) at the next

Supervisory Control Design: Small Factory

The following example, Small Factory (SF), is an illustration of supervisor design. As in Fig. 5, SF consists of two machines **MACH1** and **MACH2** each similar to **MACH** above, connected by a buffer **BUF** of capacity 2. In case of breakdown the machines can be repaired by a **SERVICE** facility as shown. Transition structures of the machines and design specifications are also displayed in Fig. 5. Σ_c (Σ_u) are odd (even) numbered events. When self-looped with all irrelevant events to form **BUFSPEC**, the latter specifies that the machines must be controlled in such a way that **BUF** is not overflowed (an attempt by **MACH1** to deposit a workpiece in **BUF** when it is full) or subject to underflow (an attempt by **MACH2** to take a workpiece from **BUF** when it is empty). In addition, **SERVICE** must enforce priority of repair for **MACH2**: when the latter is down, repair of **MACH1** (if in progress) must be interrupted and only resumed after **MACH2** has been repaired; this logic is expressed by **BRSPEC** (appropriately self-looped). To form the plant model $\mathbf{G}$ for the DES to be controlled, we compute the synchronous product of **MACH1** and **MACH2**. The result, say $\mathbf{G} = \mathbf{FACT}$, is a DES of which the components **MACHi** are free


Supervisory Control of Discrete-Event Systems, Fig. 5 Small factory

to execute their events independently except for synchronization on events that are shared (here, none). Similarly we form the synchronous product of **BUFSPEC** and **BRSPEC** to obtain the full specification DES **SPEC**. We now execute the optimization step in the Hasse diagram (Fig. 3); this yields the SF controller **KSUP**(21,47) with 21 states and 47 transitions. Online synchronization of **KSUP** with **FACT** will result in generation of the optimal controlled behavior $K_{\sup}$ by the feedback loop. Since $K_{\sup} \subseteq L_m(\mathbf{G})$ by (8), our marking conventions ensure that **KSUP** is nonblocking.

In general the language $K_{\sup}$ will include in its structure not only the constraints required by control but also the physical constraints enforced by the plant structure itself (here, **FACT**). The latter are thus redundant in the online synchronization of the plant with the controller **KSUP**. A more economical controller is obtained if the plant constraints are projected out of **KSUP** to obtain a reduced controller, say **KSIM**. Mathematically, projection amounts to constructing a control congruence or dynamically (and control) consistent partition on the state set of **KSUP** and taking the cells of this partition, abstractly, as the new

states for **KSIM**. In SF **KSUP** (21,47) is reduced to **KSIM**(5,18), which when synchronized with **FACT** yields exactly **KSUP** but is less than one-quarter the state size. In practice a state size reduction factor of ten or more is not uncommon.

Supervisor Architecture and Computation

As noted earlier, the state size |**KSUP**| of controller **KSUP** is on the order of the product of state sizes of the plant, say |**PLANT**|, and specification, say |**SPEC**|. As these in turn are the synchronous products of individual plant components or partial specifications, |**KSUP**| tends to increase exponentially with the numbers of plant components and specifications, the phenomenon of exponential state space explosion. The result is that centralized or monolithic controllers such as **KSUP** can easily reach astronomical state sizes in realistic industrial models, thereby becoming infeasible in terms of computer storage for practical design. This issue can be addressed in two basic ways: by decentralized and hierarchical architectures, possibly in heterarchical

combination, and by symbolic DES representation and computation, where what is stored are not DES and their controller transition structures in extensional (explicit) form, but instead intensional or algorithmic recipes from which the required state and control variable evaluations are computed online when actually needed.

Supervisory Control Under Partial Observations

Hierarchical control is one example of control under partial observations, a high-level manager (say) observing not full low-level operation but rather an abstraction. Partial observation has been studied mainly for abstractions given by natural projections. For a DES $\mathbf{G}$ over alphabet Σ, let $\Sigma_o \subseteq \Sigma$ be a subalphabet interpreted as the events that can be recorded by some external observer. A mapping $P : \Sigma^* \rightarrow \Sigma_o^*$ is called a natural projection if its action is simply to erase from a string s in Σ^* all the events in s (if any) that do not belong to Σ_o, while preserving the order of events in Σ_o. P extends naturally to a mapping of languages over Σ. One can then implement an induced operator on DES, say Project $(\mathbf{G}) = \mathbf{PG}$, with semantics

$$L_m(\mathbf{PG}) = PL_m(\mathbf{G}), L(\mathbf{PG}) = PL(\mathbf{G}).$$

While in worst cases $|\mathbf{PG}|$ can be exponentially larger than $|\mathbf{G}|$, such blowup seems to be rare, and typically $|\mathbf{PG}| \leq |\mathbf{G}|$, namely, P results in simplification of the model $\mathbf{G}$. By use of P it is possible to carry over to DES the control-theoretic concept of observability. Two strings $s, s' \in \Sigma^*$ are look-alikes with respect to P if $Ps = Ps'$, namely, are indistinguishable to an observer (or channel) modeled by P. Thus, given $\mathbf{G}$ and P as above, a sublanguage $K \subseteq L(\mathbf{G})$ is observable if, roughly, look-alike strings in $\overline{K}$ have the same one-step extensions in $\overline{K}$ that are compatible with membership in $L(\mathbf{G})$ and also satisfy a consistency condition with respect to membership in $L_m(\mathbf{G})$. For control under observations through P, one defines a supervisory

control function $V : L(\mathbf{G}) \rightarrow Pwr(\Sigma)$ to be feasible if it assumes the same value on look-alike strings, in other words respects the observation constraint enforced by P. It then turns out that a language $K \subseteq L_m(\mathbf{G})$ can be synthesized in a feedback loop including $\mathbf{G}$ and the feedback channel P if and only if K is both controllable and observable.

Although this result is conceptually satisfying, it is computationally inconvenient because, by contrast with controllability, the property of sublanguage observability is not in general closed under union. A substitute for observability is sublanguage normality, a stronger property than observability but one that is indeed closed under union. Since the family of controllable and normal sublanguages of a given specification language is nonempty (the empty language belongs) and is closed under union, a (unique) supremal (or optimal) element exists and can be computed; it therefore solves the problem of supervisory control under partial observations, albeit under the normality restriction. The latter has the feature that the resulting supervisor can only disable a controllable event if the latter is observable, i.e., belongs to Σ_o. In some applications this restriction might preclude the existence of a solution altogether; in others it could be harmless, or even desirable as a safety property, in that if the intended disablement of a controllable event happened to fail, and the event occurred after all, the fault would necessarily be observable and thus optimistically remediable in good time.

An intermediate property is known that is weaker than normality but stronger than observability, called relative observability. The family of relatively observable sublanguages of a given specification language is closed under union and thus does possess a supremal element, which in the regular case can be effectively computed. When combined with controllability, relative observability yields a solution to the problem of supervisory control under partial observations which places no limitation on the disablement of unobservable controllable events. Examples show that a nontrivial solution of this type may exist in cases where the normality solution is empty.

Summary and Future Directions

Supervisory control of discrete-event systems, while relatively new, has reached a first level of maturity in that it is soundly based in a standard framework of (especially) finite-state machines and regular languages. It has effectively incorporated its own versions of control-theoretic concepts like stability (in the sense of nonblocking), controllability, observability, and optimality (in the sense of maximal permissiveness). Modular architectures and, on the computational side, symbolic approaches enable design of both monolithic and heterarchical/distributed controllers for DES models of industrial size. Major challenges remain, especially to develop criteria by which competing architectures can be meaningfully compared and to organize control functionality in ways that are not only tractable but also transparent to the human user and designer.

Switching Adaptive Control

Minyue Fu
School of Electrical Engineering and Computer Science, University of Newcastle, Callaghan, NSW, Australia

Abstract

Switching adaptive control is one of the advanced approaches to adaptive control. By employing an array of simple candidate controllers, a properly designed monitoring function and switching law, this approach is capable to search in real time for a correct candidate controller to achieve the given control objective such as stabilization and set-point regulation. This approach can deal with large parameter uncertainties and offers good robustness against unmodelled dynamics. This article offers a brief introduction to switching adaptive control, including some historical background, basic concepts, key design components, and technical issues.

Keywords

Adaptive control; Hybrid systems; Multiple models; Supervisory control; Switching logic; Uncertain systems

Introduction

Switching adaptive control, also known as *switched adaptive control* or *multiple model adaptive control,* refers to an *adaptive control* technique which deploys a set of controllers and a switching law to achieve a given control objective. The concept of switching adaptive control is generalized from the traditional *gain scheduling* technique (Leith and Leithead 2000). As in the standard adaptive control setting, the model for the controlled plant is assumed to contain uncertain parameters, and the control objective is to stablize the system and, in many cases, to deliver certain performance using

real-time information in the measured output. What differentiates switching adaptive control from gain scheduling is that the uncertain parameters are not directly measured and the switching is determined by the system response. This seemingly minor difference is very important because parameter estimation may not be possible due to the lack of persistent excitation; moreover, the sensitivity of the measured output is often suppressed by the feedback control which makes closed-loop identification of the uncertain parameters difficult. Compared with classical adaptive control, switching adaptive control has better inherent robustness against parameter uncertainties and unmodelled dynamics.

By early 1980s, the classical adaptive control theory for linear systems had been well established under a set of so-called classical assumptions, which include:

- Known order of the plant (or known maximum order of the plant)
- Known relative degree of the plant
- Minimum phase dynamics
- Known sign of the high-frequency gain (which is the gain of the plant when the input is high-frequency sinusodial signal)

At the same time, it was recognized that the classical adaptive control approach has inherent robustness problems against even miniature unmodelled dynamics (Rohrs et al. 1985). While this generated a wave of research aiming at robustification of the classical adaptive control theory (see, e.g., Ioannou and Sun 1996), a new line of research took place aiming at relaxing the classical assumptions. Nussbaum (1983) paved the way by showing that knowledge of the sign of the high-frequency gain can be avoided for a first order linear system. Morse (1985) developed a "universal controller" which can adaptively stablize any strictly proper, minimum-phase system with relative degree not exceeding two. Martensson (1985) gave a very surprising result by showing that asymptotic stabilization can be achieved adaptively by simply assuming that there exists a finite order stabilizer. But Martensson's controller is impractical due to the need for exhaustive online search of the stabilizer and subsequent excessively high overshoots. Switching adaptive

control was then introduced in Fu and Barmish (1986), aiming at achieving adaptive stabilization with minimal assumptions and a guarantee of exponential convergence rate for the state. In contrast to the work of Martensson, a compactness requirement is made on the set of possible plants and an upper bound on the order of the plant is assumed. These assumptions allow a set of possible plants to be partitioned into a finite number of subsets, with each stabilizable by a single controller. A monitoring function and a switching law are then designed to sequentially eliminate incorrect candidate controllers until an appropriate controller is found. Due to the fact that the number of candidate controllers may be large, many follow-up works on switching adaptive control focused on speeding up the switching process by eliminating incorrect candidate controllers without trying them (Zhivoglyadov et al. 2000, 2001). These results can also deal with slowly time-varying parameters and infrequent parameter jumps.

Another major breakthrough came from the works of Morse (1996, 1997) under the term of *supervisory control*. His work considers set-point regulation for uncertain linear systems. A different compactness requirement is used to allow unmodelled dynamics in the system. More specifically, the given uncertain linear system is assumed to belong to a union of sub-families of systems, with each sub-family having a linear controller capable to achieve set-point regulation. Suitably defined output-squared estimation errors are used as monitoring functions and a candidate controller is selected whose corresponding performance signal is the smallest. The major advantages of this switching law are that the "correct" controller can usually be quickly identified without cycling through all possible candidate controllers, leading to a good closed-loop performance.

More recent research on switching adaptive control focuses on more systematic and alternative approaches to the design of candidate controllers and switching laws; see, e.g., Anderson et al. (2000), Hespanha et al. (2001), and Morse (2004). Generalizations to nonlinear systems are also found Battistelli et al. (2012).

Design of Switching Adaptive Control

A switching adaptive controller consists of the following key ingredients:

- Design of control covering
- Design of monitoring function
- Selection of dwell time

For illustrative purposes, we consider an adaptive stabilization problem where the system has the following model:

$$\dot{x}(t) = Ax(t) + Bu(t)$$
$$y(t) = Cx(t)$$

with state $x(t) \in R^n$ for some $1 \leq n \leq n_{\max}$ and the measured output $y(t) \in R^r$. The given set of uncertain plants Σ consits of triplets (A, B, C) and we use the notation $\Sigma^{(n)}$ to denote the subset of Σ consisting of those plants having order n. It is assumed that every possible plant $(A, B, C) \in \Sigma$ is a minimal realization (i.e., both controllable and observable) and that every $\Sigma^{(n)}$ is a compact set (i.e., it is closed and bounded). The control objective is to design an adaptive controller to drive the state to zero asymptotically, i.e., $x(t) \rightarrow 0$ as $t \rightarrow \infty$. It is clear that each possible plant in Σ admits a linear dynamic stabilizer. An alternative description of the uncertain plant is introduced in Morse (1996, 1997) where its transfer function is a member of a continuously parameterized set of admissible transfer functions of the form

$$\Sigma \subset \bigcup_{p \in \mathcal{P}} \{v_p + \delta : \|\delta\| \leq \varepsilon_p\}$$

In the above, $\mathcal{P}$ is a compact set in a finite dimensional space, v_p is a nominal transfer function with its coefficients depending continuously on p, δ is the transfer function of some unmodelled dynamics, $\|\delta\|$ represents a shifted H_∞ norm (obtained by first shifting the poles of δ slightly to the right and then computing its H_∞ norm), and ε_p is sufficiently small so that each set of plants $\{v_p + \delta : |\delta| \leq \varepsilon\}$ is stabilizable by a single controller for all $p \in \mathcal{P}$.

Control covering: The purpose is to decompose the given set of plants into a union of subsets such that each subset P_i admits a single controller K_i (called candidate controller) to achieve the given control objective. This is typically done using two properties: inherent robustness of linear controllers and the existence of a finite cover for any compact set. More specifically, if a candidate controller renders a desired control objective for a given plant, then the same objective is maintained when the plant is perturbed slightly. For example, Fu and Barmish (1986) uses the fact that if a given plant is stabilized by a controller then the same controller stabilizes all the plants with sufficiently small parameter perturbations. Similarly, Morse (1996, 1997) uses the fact that the same controller achieves set-point regulation for a small neighborhood of plants. Combining this property with the finite covering property yields

$$\Sigma = \bigcup_{i=1}^{N} \Sigma_i$$

such that each subset Σ_i admits a single controller K_i.

Monitoring Function: The generation of the adaptive switching controller is accomplished using a *switching law* or *switching logic* whose task is to determine, at each time instant, which candidate controller is to be applied. The core of the switching law is a monitoring function. Its very basic role is to be able to detect whether the applied candidate controller is consistent with the corresponding plant subset so that wrong candidate controllers can be eliminated one by one until an appropriate controller is found. A major difficulty for switching adaptive control design is that persistent excitation is not assumed. Consequently, it is not always possible to detect the correct plant subset using the measured output. The key idea is to check which plant subsets are consistent with the generated output.

One simple monitoring function uses a finite-time L_2 norm of the measured output:

$$V(t, \tau) = \int_{t-\tau}^{t} \|y(s)\|^2 \, ds$$

where τ is the so-called *dwell time*. It turns out that for some properly chosen dwell time, a correctly applied candidate controller is able to guarantee some decay property for the monitoring function, i.e., $V(t, \tau) \leq e^{-\lambda \tau} V(t - \tau, \tau)$ for some $\lambda > 0$. This property is sufficient to allow a wrong candidate controller to be eliminated. However, much smarter monitoring functions can be designed so that infeasible candidate controllers (those not corresponding to the true plant) can be eliminated without even being applied. This can be done using the *falsification* approach in parameter estimation where the basic idea is to eliminate all plant subsets Σ_i inconsistent with the measured output signal. For example, consider the following discrete-time model:

$$y(t) = -a_1 y(t-1) - a_2 y(t-2)$$
$$+ b_1 u(t-1) + b_2 u(t-2) + w(t)$$

where a_i and b_i are uncertain parameters and w(t) is a bounded disturbance, i.e., $|w(t)| \leq \delta$ for some δ. For this example, we may eliminate all the uncertain parameter subsets which violate the following constraint (Zhivoglyadov et al. 2000):

$$|y(t) + a_1 y(t-1) + a_2 y(t-2)$$
$$- b_1 u(t-1) - b_2 u(t-2)| \leq \delta$$

More generally, one can use the so-called multi-estimator (Morse 1996, 1997) which involves an array of estimators, one for each plant subset Σi using its nominal model. The output estimation error $e, (l)$ for each such estimator is then used to construct a monitoring function, e.g.,

$$V_i(t, \tau) = \int_{t-\tau}^{t} e^{-2\lambda(t-s)} \|e_i(s)\|^2 \, ds$$

where τ is the dwell time as before and $\lambda > 0$ is an exponential weighting parameter used to guarantee the decay rate of the monitoring function as before. Instead of using the monitoring functions to eliminate infeasible candidate controllers, the candidate controller corresponding to the least estimation error, as measured by the least monitoring function, is selected. The main advantage of the multi-estimator based monitoring functions is that falsification of candidate controllers is done implicitly and a "correct" controller can be quickly reached, leading to good performance.

Dwell Time: The dwell time τ as defined above is a critical component in switching adaptive control. Serving in the monitoring function, this is the minimum nonzero amount of time for a candidate controller to be applied before switching. That is, this provides a sufficient time lag to build the monitoring function so that its exponential decay property is detected when a correct candidate controller is applied. This will allow detection of infeasible plant subsets and selection of a "correct" controller. The use of a dwell time also avoids arbitrarily fast switching, thus gaurantee-ing the solvability of the system dynamics.

The dwell time can be selected a priori by using the fact that if a matrix A is stable, then there exist some positive values λ and τ such that $\|e^{At}\| \leq e^{-\lambda \tau}$ for all $i > \tau$. This leads to the desired exponential decaying property

$$V(t, \tau) \leq e^{-\lambda \tau V}(t - \tau, \tau)$$

for the aforementioned monitoring function for adaptive stabilization.

Alternatively, the dwell time can be chosen implicitly. Hespanha et al. (2001) suggest a *hysteresis switching logic* method. This method employs a hysteresis parameter $h > 0$. Suppose the candidate controller K_j is applied at time t_i, then K_j is kept until the next switching time t_{i+1} which is the minimum $t \leq t_i$, such that

$$(1 + h) \min_{1 \leq k \leq N} V_k(t, t - t_i) \leq V_j(t, t - t_i)$$

Because h > 0, the time difference $t_{l+1} - t_i > 0$ is lower bounded, which implies the existence of a dwell time.

Summary and Future Directions

Switching adaptive control is a conceptually simple control technique capable to deal with large

S

parameter uncertainties. The use of simple candidate controllers (typically linear) imply good closed-loop behavior and good robustness against unmodelled dynamics. Although the discussion above assumes that the number of plant subsets is finite, this assumption is not essential; see Anderson et al. (2000).

Switching adaptive control renders the closed-loop system a switched system or hybrid system, for which a wide range of tools are available to aid the analysis of such a system; see, e.g., Liberzon (2003). However, unique features of such a system arise from the fact that the switching mechanism is chosen by the designer, rather than being a part of the given plant. How to best design the switching mechanism is an interesting issue.

Future works for switching adaptive control include:

1. How to simplify the design of candidate controllers. Finite covering based design often yields a large number of plant subsets, hence a large number of candidate controllers. Since most of the candidate controllers do not need to apply (which is the case when falsification based switching logic is used, for example), smarter ways are needed for the design of candidate controllers.

2. Wider applications. Most of the research so far focuses on stabilization and set-point regulation (which is essentially a stabilization problem). How to incorporate general performance criteria is an essential and yet challenging issue.

3. Better design of monitoring functions and the corresponding switching logic. Most existing monitoring functions use a finite-time L_2 norm of the output (or regulation error), with the key feature that some exponential decay property is guaranteed when the candidate controller is "correct." Note that the key purpose of the monitoring function and the corresponding switching logic is to allow fast falsification of infeasible candidate controllers. Thus, a much wider range of monitoring functions can possibly be used. In particular, how to incorporate set membership identification techniques (Milanese and Taragna 2005) may be of particular interest.

Abstract

In this entry we review the theory of optimal
synthesis. We describe the steps necessary to
solve an optimal control problem and the suf-
ficient conditions for optimality given by the
theory. We describe some relevant examples that
have important applications in mechanics, in the
theory of hypo-elliptic operators and for the study
of models of geometry of vision. Finally, we
discuss the problem of optimal stabilization and
the difficulties encountered if one tries to give the
solution to the problem in feedback form.

Keywords

Affine control systems; Extremals; Pontryagin
Maximum Principle; Sub-Riemannian geometry;
Time-optimal synthesis

Optimal Control

An optimal control problem with fixed initial and
terminal conditions can be seen as a problem
of calculus of variations under nonholonomic
constraints:

$$\dot{q}(t) = f(q(t), u(t)), \tag{1}$$

$$\int_0^T L(q(t), u(t))\, dt \rightarrow \min \quad (T \text{ fixed or free}), \tag{2}$$

$$q(0) = q_0, \quad q(T) = q_1. \tag{3}$$

Here we make the following set of assumptions:

(H) q belongs to a finite-dimensional smooth
manifold M of dimension n. As a function of
time $q(.)$ is assumed to be Lipschitz continuous.
The control $u(.)$ is a L^∞ function taking values
in a set $U \subset \mathbb{R}^m$. For simplicity, we assume that
the functions f and L, defined on $M \times \mathbb{R}^m$, are
smooth.

The dynamics $\dot{q}(t) = f(q(t), u(t))$ play the
role of the nonholonomic constraint (nonholo-
nomic means that it is a constraint on the velocity
but not necessarily on the position).

Solving an optimal control problem in general
is a very difficult task. Usually, to attack such a
problem, the steps are the following:

- STEP 0: EXISTENCE. First, one has to guar-
  antee the existence of a solution to (1)–(3).
  The most important sufficient condition for
  the existence of minimizers is the famous
  Filippov theorem (see for instance Agrachev
  and Sachkov (2004) for a proof) saying the
  following: introduce a new variable (the so-
  called augmented state) $\hat{q} := (q^0, q) \in
  \mathbb{R} \times M$ satisfying the following dynamics:

$$\dot{\hat{q}}(t) = \begin{pmatrix} \dot{q}^0(t) \\ \dot{q}(t) \end{pmatrix} = \begin{pmatrix} L(q(t), u(t)) \\ f(q(t), u(t)) \end{pmatrix}$$

$$=: \hat{f}(\hat{q}(t), u(t)) \tag{4}$$

then if (i) U is compact; (ii) the set of ve-
locities $F(\hat{q}) := \{\hat{f}(\hat{q}, u) \mid u \in U\}$ is
convex for every $\hat{q}$; (iii) for every $T > 0$ and
$\hat{q}_0 \in \mathbb{R} \times M$, there exists a compact set $K \subset
\mathbb{R} \times M$ such that all solutions of (4) starting
from $\hat{q}_0$ stay in K for $t \in [0, T]$; then there
exist Lipschitz minimizers. Other theorems
that can be applied in more general functional
classes or under less restrictive hypotheses can

S

be found in the literature. See for instance Bressan and Piccoli (2007), Cesari (1983), and Vinter (2010).

- STEP 1: FIRST ORDER NECESSARY CONDITIONS. In optimal control, the first order necessary conditions for optimality are given by the celebrated Pontryagin Maximum Principle (Pontryagin et al. 1961) (see also Agrachev and Sachkov (2004) for a more recent viewpoint). The Pontryagin Maximum Principle (PMP for short) extends the (Hamiltonian version of the) Euler-Lagrange equations of calculus of variations to problems with nonholonomic constraints. For a discussion about the relation between variational problems under nonholonomic constrains and variational principles in nonholonomic mechanics, see Bloch (2003).

The PMP restricts the set of candidate optimal trajectories starting from q_0 to a family of trajectories, called *extremals*, parameterized by a covector $p(0) \in T_{q_0}^* M$. In addition, there are two kinds of special extremals: (i) the *singular extremals* for which the maximization condition given by the PMP does not permit directly obtaining the control and (ii) the *abnormal extremals* which are candidate optimal trajectories for any cost function. For certain classes of problems, abnormal extremals and singular trajectories coincide.

The set of all trajectories satisfying the PMP (in general having intersections and not being all optimal forever) is called an *extremal synthesis*. The requirement that the trajectories starting from q_0 reach the final point q_1 (at time T, fixed or free) is usually not very useful at this step. This requirement is rather made at STEP 4.

- STEP 2. HIGHER ORDER CONDITIONS. Higher order conditions are used to restrict further the set of candidate optimal trajectories. The most important conditions are those used to eliminate singular extremals (which usually are very hard to treat) as the Goh condition and the generalized Legendre-Clebsch conditions (see for instance Agrachev and Sachkov 2004). Other theories that provide higher order conditions (which apply

also to extremals that are not singular) are for instance: higher order maximum principles (Bressan 1985; Krener 1977), generalized Morse-Maslov index theories (Agrachev and Sachkov 2004), and envelope theory (Sussmann 1986, 1989, see also Boscain and Piccoli 2004, Cap. 1.3.2).

- STEP 3. SELECTION OF THE OPTIMAL TRAJECTORIES. This step is the most difficult one. Indeed, one should check that each extremal of the extremal synthesis does not intersect another extremal having a smaller cost at the intersection point. This comparison should be done not only among extremals which are close, one to the other, but among all of them. The problem is indeed global.

One of the techniques to address this problem in a very elegant way takes the name of *optimal synthesis theory*, and was developed almost together with the birth of the Pontryagin Maximum Principle. This theory dates back to the paper of Boltyanskii (1966) and was further developed by Brunovsky (1980, 1978), Sussmann (1980, 1979), and Piccoli and Sussmann (2000).

Roughly speaking, the theory of optimal synthesis permits to conclude that if one has an extremal synthesis having certain regularity properties, then this extremal synthesis is indeed an optimal synthesis.

An optimal synthesis is a collection of optimal trajectories starting from q_0 and reaching the various points of the space:

$$\mathcal{S}_{q_0} = \{\gamma_q(.) : [0, T_q] \to M \,|\, q \in M, \gamma_q \text{ is}$$
a trajectory of (1) minimizing the cost $\int_0^{T_q} L(q(t), u(t)) \, dt$ with $\gamma(0) = q_0, \ \gamma(T) = q\}$

An optimal synthesis should also verify the following condition: if γ_q defined on $[0, T]$ and γ_q' defined on $[0, T']$ (with $T' \in]0, T[$) belong to $\mathcal{S}_{q_0}$ and we have $q' = \gamma_q(T')$ then $\gamma_{q'} = \gamma_q|_{[0,T']}$. More details are given in the next section.

- STEP 4. SELECTION OF THE TRAJECTORY REACHING THE FINAL POINT. Once an optimal synthesis is computed,

one selects the optimal trajectory reaching the desired final point solving the equation $\gamma(T) = q_1$, in the set of all trajectories belonging to the optimal synthesis.

Remark 1 Notice that one could require that the final point is reached at STEP 1. This would considerably reduce the set of candidate optimal trajectories already at STEP 1, but would not permit to apply the powerful (global) theorems of STEP 3. As a consequence, one would be obliged to compare by hands all extremals going from q_0 to q_1.

Sufficient Conditions for Optimality: The Theory of Optimal Synthesis

There exists a general principle for which every synthesis formed by extremals is optimal under very mild regularity conditions. We will illustrate a classical case of a feedback smooth on a stratification, due to Boltianskii and Brunovsky, see Boltyanskii (1966) and Brunovsky (1980, 1978). More general results can be found in Piccoli and Sussmann (2000). This principle is very strong and is valid only because the synthesis is a global object, while given a single trajectory satisfying PMP, there is no regularity condition which ensures optimality.

For simplicity, from now on, we assume that $M = \mathbb{R}^n$ is an Euclidean space and $q_0 = 0$ and indicate by $\mathcal{S}$ a candidate optimal synthesis from 0, the general case follows easily. A set $P \subset M$ is said a *curvilinear open polytope* of dimension p, if there exists a polytope (i.e., bounded closed region intersection of a finite number of half-spaces) $P' \subset \mathbb{R}^p$ and a smooth map $\phi : \mathbb{R}^p \to \mathbb{R}^n$, injective with jacobian having maximal rank at every point, such that $\phi(P' \setminus \partial P') = P$.

Let Ω be an open subset of M (for the induced topology) containing the origin in its interior. We say that $\mathcal{S}$ is a *Boltyanskii–Brunovsky regular synthesis*, briefly BB synthesis, if the following holds.

There exists a 6–tuple $\Xi = (\mathcal{P}, \mathcal{P}_1, \mathcal{P}_2, \prod, \Sigma, u)$ such that

(BB1) $\mathcal{P}$ is a collection of curvilinear open polyhedra and Ω is disjoint union of elements of $\mathcal{P}$. If $P_j \neq P_k \in \mathcal{P}$ and $P_k \cap \overline{P_j} \neq \emptyset$ then $P_k \subset \partial P_j$ and $\dim(P_k) < \dim(P_j)$. $\{0\} \in \mathcal{P}$ and the elements of $\mathcal{P}$ are called "cells".

(BB2) $\mathcal{P} \setminus \{\{0\}\}$ is the disjoint union of $\mathcal{P}_1$ (the set of "type I cells") and $\mathcal{P}_2$ (the set of "type II cells"),

(BB3) the feedback $u : \{q : \exists P_1 \in \mathcal{P}_1, q \in P_1\} \to U$ and $\prod : \mathcal{P}_1 \to \mathcal{P}$ are maps, $\Sigma : \mathcal{P}_2 \to \mathcal{P}_1$ is a multifunction, with non empty values, such that the following properties are satisfied:

(i) The function u is of class $\mathcal{C}^1$ on each cell.

(ii) If $P_1 \in \mathcal{P}_1$, then $f(q, u(q)) \in T_q P_1$ (the tangent space to P_1 at q) for every $q \in P_1$. In addition, for each $q \in P_1$, if we let ξ_q be the maximally defined solution to the initial value problem

$$\dot{\xi} = f(\xi, u(\xi)), \quad \xi(0) = x, \quad \xi \in P_1, \tag{5}$$

and define $t_q = \sup Dom(\xi_q)$, then the limit $\xi_q(t_q-) := \lim_{t \uparrow t_q} \xi_q(t)$ exists and belongs to $\prod(P_1)$.

(iii) If $P_2 \in \mathcal{P}_2$, then for each $q \in P_2$ and $P \in \Sigma(P_2)$ there exists a unique curve $\xi_q^P : [0, t_q^P[\to \Omega$ such that the restriction of ξ_q^P to $]0, t_q^P]$ is a maximally defined integral curve of the vector field $f(\cdot, u(\cdot))$ on P, and $\xi_q^P(0) = q$.

(iv) On every cell $P_1 \in \mathcal{P}_1$, $q \to t_q$ is a continuously differentiable function, and $(t, q) \to \xi_q(t)$, $(t, q) \to u_q(t) := u(\xi_q(t))$ are continuously differentiable maps on the set

$$E(P) := \{(t, q) : q \in P_1, t \in [0, t_q]\}.$$

If $P_2 \in \mathcal{P}_2$ the same holds for every t_q^P, ξ_q^P, u_q^P, with $P \in \Sigma(P_2)$.

(v) For every $q \in \Omega \setminus \{0\}$, the trajectory $\gamma_q : [0, T_q] \to M, \gamma_q \in \mathcal{S}$, is obtained by piecing together the trajectories on every single cell. Moreover, γ_q changes cell a finite number of times.

S

Theorem 1 (Sufficiency theorem for BB synthesis) *Let $\mathcal{S}$ be a BB synthesis on M formed by extremal trajectories, then $\mathcal{S}$ is optimal.*

Remark 2 Theorem 1 can be proved also for synthesis on an open subset Ω of M, under suitable conditions, see Piccoli and Sussmann (2000).

Some Relevant Examples

Even if the sufficient conditions for optimality given by the theory of optimal synthesis are very powerful, in general computing explicitly an optimal synthesis is very hard and the complexity grows quickly with the dimension of the space. The main difficulties are:

- The integration of the Hamiltonian equations given by the PMP (which in general is not integrable, unless there are many symmetries);
- The characterisation of singular and abnormal extremals;
- The verification of the hypotheses of the sufficient conditions for optimality given by synthesis theory.

For these reasons, the computation of optimal synthesis is already challenging in dimension 2, and few examples have been solved in dimension 3. In higher dimensions, only very symmetric problems have been completely solved. In the following, we list some of the most relevant optimal synthesis that have been computed up to now.

Time-Optimal Synthesis for Affine Control Systems on 2-D Manifolds

Let M be a 2-D manifold and consider the problem of finding the time-optimal synthesis starting from a point q_0 for a system of the type

$$\dot{q} = F(q) + uG(q), \quad |u| \leq 1, \quad F(q_0) = 0 \tag{6}$$

Here we assume that F and G are Lie-bracket generating. The condition $F(q_0) = 0$ guarantees local controllability around q_0, for a generic pair (F, G). A complete theory for this kind of systems, was developed in Bressan and Piccoli (1998), Piccoli (1996), and Boscain and Piccoli (2004), under generic conditions on the vector fields F and G. More precisely, in Boscain and Piccoli (2004) it was provided: (i) an algorithm building explicitly the time-optimal synthesis; (ii) a classification of synthesis in terms of graphs; (iii) a classification of synthesis singularities; (iv) an analysis of the properties of the minimum time function.

Here we just recall that optimal trajectories are a finite concatenation of bang (trajectories corresponding to constant control $+1$ or -1) and singular arcs (for which the control may correspond to something different from $+1$ or -1).

Under generic conditions, the optimal synthesis provides a stratification of M. In the regions of dimension 2, the control is either $+1$ or -1. The regions of dimension 1 called *Frame Curves* can be: (i) arcs of optimal trajectories (that may be bang or singular); (ii) switching curves (i.e., curves made of points in which the control switches from $+1$ or -1, or viceversa); (iii) overlap curves (i.e., curves made of points where the extremals lose their optimality). The region of dimension 0 called *Frame Points* are points where frame curves intersect. Generically, they can be of 23 types. See Boscain and Piccoli (2004, p. 60).

Some Relevant Time-Optimal Synthesis for 3D Problems

As we saw in the previous section, for minimum time problems in dimension 2, many results can be obtained, and in most cases a time-optimal synthesis can be constructed. The situation is different for time-optimal problems in dimension 3. Indeed, beside trivial cases, the time-optimal synthesis was computed in full details for few examples only. One is the Reed and Shepp's car,

$$\begin{pmatrix} \dot{x} \\ \dot{y} \\ \dot{\theta} \end{pmatrix} = u_1 \begin{pmatrix} \cos\theta \\ \sin\theta \\ 0 \end{pmatrix} + u_2 \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix}, \quad |u_1|, |u_2| \leq 1. \tag{7}$$

The time-optimal synthesis for this problem was computed in Soueres and Laumond (1996). The extreme complexity of the optimal synthesis obtained for this simple example had the effect that no other time-optimal synthesis in dimension 3 or larger, with one or two bounded controls, were computed up to the last 2-years.

Very recently, the interest in time-optimal synthesis for systems of the type

$$\dot{q} = \sum_{i=1}^{m} u_1 F_i(q), \quad |u_i| \leq 1, \quad (i = 1, \ldots, m) \tag{8}$$

where q belongs to a n-dimensional manifold and $2 \leq m \leq n$, has attracted new attention.

This is indeed a problem of nonstrictly convex sub-Finsler geometry that appears in the study of asymptotic cones of nilpotent groups in geometric group theory (Gromov 1981; Breuillard and Le Donne 2012).

Sub-Riemannian Geometry

A very important class of optimal control problems is the one called sub-Riemannian. Let M be a n-dimensional manifold ($n \geq 2$) and consider the problem of finding the time-optimal synthesis starting from a point q_0 for the problem

$$\dot{q} = \sum_{i=1}^{m} u_i F_i(q), \quad \int_0^1 \sqrt{\sum_{i=1}^{m} u_i^2} \, dt \to \min,$$
$$(2 \leq m \leq n) \tag{9}$$

Here we assume that the family of vector fields $\{F_i\}_{i=1\ldots m}$ is Lie-bracket generating. This kind of optimal-control problems includes Riemannian geometry and many of its generalizations that usually take the name of sub-Riemannian geometry (see Bellaiche (1996), Montgomery (2002) and the pioneering work by Brockett (1982)). The complete time optimal synthesis was computed in a few relevant cases:

- The Heisenberg group (Gaveau 1977; Gershkovich and Vershik 1988).
- The local 3-dimensional contact case, under generic conditions (Agrachev 1996; El-Alaoui et al. 1996).

- Some relevant left-invariant problem on simple Lie groups, i.e., $SO(3)$, $SU(2)$, $Sl(2)$, see Boscain and Rossi (2008).
- The left-invariant problem on the group of rototranslation $SE(2)$ that has important applications in models of geometry of vision (Boscain et al. 2012; Sachkov 2011; Petitot 2008).
- In dimension bigger than 3, only the quasi-Heisenberg case (Charlot 2002) and certain multidimensional generalizations of the Heisenberg case has been computed (Beals et al. 1996).
- In dimension 2, problems of type (8) are called problems of *almost-Riemannian geometry*. The basic example (the so-called Grushin case) was studied in Bellaiche (1996) and the study of the synthesis in the generic case, permitted to obtain some generalizations of the Gauss-Bonnet theorem (Agrachev et al. 2008).

Some of the synthesis mentioned above permitted to obtain important results for the theory of hypoelliptic operators (Hormander 1967). Moreover, they permitted to clarify the relation between small-time heat kernel asymptotics and the properties of the value function for the problem (9). See for instance Barilari et al. (2012) and references therein.

Connections with the Stabilization Problem

Consider now the control system $\dot{q}(t) = f(q(t), u(t))$, under the hypothesis (H). Fix $q_0 \in M$ and assume that there exists $u_0 \in U$ such that $f(q_0, u_0) = 0$. A stabilization problem can be stated as follows:

(**P**): For every $\bar{q} \in M$, find a trajectory of the control system $\dot{q}(t) = f(q(t), u(t))$, (under hypothesis (H)) with boundary conditions $q(0) = \bar{q}$, $q(T) = q_0$. (Here T could be required to be finite or not, depending on the problem.)

An elegant way of giving a solution to the problem (**P**) is to give a stabilizing feedback, namely

a function $K(q)$ such that for every $\bar{q} \in M$ the solution of

$$\dot{q}(t) = f(q(t), K(t)) \qquad (10)$$

with initial condition $q(0) = \bar{q}$ steers $\bar{q}$ to q_0.

It is well known that in general it is not possible to give the solution to (**P**) in feedback form. Indeed there may be topological constraints (in the sense of Brockett, see for instance Brockett (1983)) that prevent such a feedback to be continuous. Hence, in general, one cannot guarantee existence and uniqueness of classical or Caratheodory solutions to the ODE (10). This problem attracted a lot of attention since the pioneering work of Brockett and several approaches have been proposed: e.g., via generalized concept of solutions, patchy feedback, time varying feedback etc. (see for instance Clarke et al. 1997; Ancona and Bressan 1999; Coron 1992).

Sometimes one considers an "optimal control" variant of the problem (**P**):

(**Po**): For every $\bar{q} \in M$, find the trajectory of the control system $\dot{q}(t) = f(q(t), u(t))$, (under hypothesis (H)) minimizing the cost $\int_0^T L(q(t), u(t)) \, dt$ (here T can be fixed or free), with boundary conditions $q(0) = \bar{q}, \ q(T) = q_0$.

The cost can be an additional constraint given by the problem, or can be added artificially to have a method and a good concept of solution to solve problem (**P**). Indeed, a way of giving the solution to problem (**Po**) (and hence to (**P**)) is to find the optimal synthesis starting from q_0 for the problem

(**–Po**): for every $\bar{q} \in M$, solve

$$\begin{cases} \dot{q} = -f(q, u), \ u \in U \\ \int_0^T L(q(t), u(t)) \, dt \to \min \\ q(0) = q_0, q(T) = \bar{q}, \end{cases}$$

and then to reverse the time. In other words if $\gamma : [0, T] \to M$ is the solution of (**–Po**) steering q_0 in $\bar{q}$, then $\gamma(T - t)$ is the solution to (**Po**) steering $\bar{q}$ in q_0. This type of solution to problem (**Po**) is called an "optimal stabilizing synthesis".

Extracting a Feedback from an Optimal Synthesis

It is interesting to see what happens if one tries to extract a feedback from an optimal stabilizing synthesis.

If each optimal trajectory of the optimal synthesis corresponds to a regular enough control (e.g., smooth or piecewise) the feedback corresponding to the optimal synthesis can be defined easily in the following way: if $(\gamma(.), u(.))$ defined in $[0, T]$ is a pair trajectory-control of the optimal synthesis, then $K(\gamma(t)) = u(t)$ for every $t \in [0, T]$.

However, as already mentioned, in most of the situations $K(q)$ is not continuous. (Notice that even in the case in which all trajectories of the optimal synthesis are smooth it may happen that $K(q)$ is not continuous.) Hence, in general, one cannot guarantee existence and uniqueness of classical or Caratheodory solutions to the ODE (10).

One could think of enlarging the concept of the solution of (10) by using Filippov, Krasowski, or CLSS (Clarke et al. 1997) solutions (see for instance Marigo and Piccoli 2002, Piccoli and Sussmann 2000 and references therein). However none of these types of solutions are adapted to give the solution of an optimal stabilization problem in feedback form. To fix the ideas, let us consider the case of Filippov solutions. In Piccoli and Sussmann (2000) the authors build examples of optimal synthesis for which the corresponding feedbacks generate solutions that are either Filippov but nonoptimal or optimal but not Filippov. The same can be done with the other types of solutions mentioned above. Also, it is possible to build an example showing an optimal stabilizing synthesis for which the corresponding feedback generates non optimal trajectories even in classical sense. This is presented in the next section.

Hence, at the moment an optimal stabilizing synthesis remains the only possible concept of solution for an optimal stabilizing problem.

Synthesis Theory in Optimal Control, Fig. 1 An optimal stabilizing synthesis for which the corresponding feedback generates nonoptimal trajectories
An Example of a Time-Optimal Synthesis Whose Feedback Generates Nonoptimal Trajectories

We present an example exhibiting the phenomenon of nonuniqueness of trajectories for the closed-loop equation arising from the feedback extracted from an optimal synthesis. In particular the optimal feedback admits nonoptimal (classical) solutions. This well illustrates the importance of using the synthesis as concept of solution for an optimal stabilization problem.

Consider the planar system:

$$\dot{q} = F(q) + u\,G(q), \qquad |u| \le 1,$$

where $q = (x, y)$ and:

$$F(q) = \begin{pmatrix} 1 - \frac{y}{2} \\ \frac{x+1}{2} \end{pmatrix}, \qquad G(q) = \begin{pmatrix} -\frac{y}{2} \\ \frac{x+1}{2} \end{pmatrix},$$

and the target is the origin.

The trajectories corresponding to the constant control equal to -1 are straight horizontal lines going from left to right, while those corresponding to $+1$ are circles centered at the point $(-1, 1)$, running counterclockwise. The optimal synthesis is described in Fig. 1. For a proof of optimality see Piccoli and Sussmann (2000).

Starting from the point $(-1, 0)$, we have an infinite number of classical solutions to the discontinuous optimal feedback. Indeed at that point we have $F + G = F - G$, so given any natural number n, the trajectory running n times on the circle centered at $(-1, 1)$ and then going to the origin with control -1 is a classical solution to the discontinuous optimal feeback. However, only the one corresponding to $n = 0$ is optimal.

About other concepts of solutions starting from $(-1, 0)$, one can prove the following. Krasowski or CLSS include classical solutions (and hence produce many nonoptimal trajectories). There is only one Filippov solution, that is the one that rotates indefinitely on the circle and never goes to the origin. This trajectory is not a solution to the stabilization problem since it does not reach the target.

Abstract

The past decade has seen tremendous advances in DNA recombination and measurement techniques. These advances have reached a point in which de novo creation of biomolecular circuits that accomplish new functions is now possible, leading to the birth of a new field called synthetic biology. Sophisticated functions that are highly sought in synthetic biology range from recognizing and killing cancer cells, to neutralizing radioactive waste, to efficiently transforming feedstock into fuel, to control the differentiation of tissue cells. To reach these objectives, however, there are a number of open problems that the field has to overcome. Many of these problems require a system-level understanding of the dynamical and robustness properties of interacting systems, and hence, the field of control and dynamical systems theory may highly contribute. In this entry, we review the basic technology employed in synthetic biology and a number of simple modules and complex systems created using this technology and discuss key system-level problems along with challenging research questions for the field of control theory.

Keywords

Biomolecular systems; Gene expression; Robustness; Modularity

Introduction to Synthetic Biology

Synthetic biology is an emerging engineering discipline in which the biochemical and biophysical principles present in living organisms are used to engineer new systems (Baker et al. 2006). These systems will have the ability of accomplishing a number of remarkable tasks, such as turning waste into energy sources, neutralizing radioactive waste, detecting environmental pathogens, or recognizing cancer cells with the aim of targeting them for deletion. While synthetic biology can be employed to create new functionalities, it can also enable the understanding of fundamental design principles of living systems. In fact, implementing a circuit with a prescribed behavior provides a powerful means to test hypotheses regarding the underlying biological mechanisms.

The functions of living organisms are controlled by biomolecular circuits, in which proteins and genes interact with each other through activation and repression interactions forming complex networks. A common signal carrier is the concentration of the active form of a protein, which can be controlled through a number of mechanisms, including gene expression regulation and post-translational

S

modification. Through the process of gene expression, proteins are produced by their corresponding genes, whose production rates can be activated or repressed by other proteins (transcription factors). Once the proteins are produced, they can be activated or inhibited, by other proteins or smaller molecules, through post-translation modification processes including covalent modification, such as phosphorylation, and allosteric modification (Alon 2007). We next describe some salient aspects of gene expression focusing, for simplicity, on prokaryotic systems.

A gene is a piece of DNA whose expression rate can often be controlled by a DNA sequence upstream of the gene itself, called promoter. The promoter contains the binding regions for the RNA polymerase, an enzyme that transcribes the gene into a messenger RNA molecule, which is then translated into protein by the ribosomes. The promoter also contains operator sites, which are binding regions where other proteins, called transcription factors, can bind. If these proteins are activators, they will help the RNA polymerase in binding the promoter to start transcription. By contrast, if these proteins are repressors, they will prevent the RNA polymerase from binding the promoter. These activation and repression inter-actions are highly nonlinear and often stochastic; therefore, the most commonly used modeling frameworks include systems of nonlinear ordinary differential equations, stochastic differential equations, or the chemical master equation (Gillespie 1977, 2000).

The basic technique for constructing synthetic circuits is that of assembling, through the process of cloning, DNA sequences with prescribed combinations of promoters and genes such that a desired network of activation and repression interaction is created. For example, if we would like to create an inverter where protein A represses protein B, we can simply place the gene of B under the control of a promoter repressed by protein A. Currently, there is a library of parts that one can use to assemble a desired circuit this way. The set of parts includes promoters, gene coding sequences, terminators, and ribosome binding sites. Terminators are DNA sequences placed at the end of a gene to make the RNA polymerase terminate transcription, while ribosome binding sites are DNA sequences placed at the beginning of a gene, which establish the rate at which ribosomes will bind to the mRNA, determining the overall translation rate (Endy 2005). An area of intense research is the expansion of the library by creating mutations of existing parts or by assembling new ones.

Once a DNA sequence is created that encodes the desired circuit, it is inserted in a living cell either on the chromosome itself or on DNA plasmids. When the circuit is inserted in the chromosome, it will be in one copy, while when it is inserted in DNA plasmids, it will be in as many copies as the plasmid copy number. Plasmid copy number can vary from low copy (5–10 copies), to medium copy (20 copies), to high copy (about 100 copies). Once in the cell, the circuit will have the required resources to function, including RNA polymerase, ribosomes, amino acids, and ATP (the cell energy currency). In this sense, the cell can be viewed as a chassis for the synthetic circuits. The operation of the circuit can then be observed by monitoring the concentration of reporters, that is, of proteins that are easy to detect and quantify. These include fluorescent proteins, that is, proteins that exhibit bright fluorescence when exposed to light of a specific wave length. Examples include the green, red, blue, and yellow fluorescent proteins. These fluorescent proteins are mainly employed in two different ways to measure the amount of a protein of interest. One can fuse the gene of the fluorescent protein with the gene expressing the protein of interest. Alternatively, one can use the protein of interest as a transcription factor of the fluorescent protein. In both cases, the concentration of the fluorescent protein will provide an indirect measurement of the concentration of the protein of interest.

It is also possible to apply external inputs to a circuit to control the activity of transcription factors. This is accomplished through the use of inducers, which are small signaling molecules that can be injected in the cell culture and enter the cell wall. These inducers bind specific transcription factors and either activate them,

allowing the transcription factor to bind the promoter operator sites, or inhibit them, reducing the transcription factor's ability to bind the promoter operator sites.

Examples of Synthetic Biology Modules

A number of modules comprising two or three genes have been fabricated in the earlier days of synthetic biology (Atkinson et al. 2003; Becskei and Serrano 2000; Elowitz and Leibler 2000; Gardner et al. 2000; Stricker et al. 2008). We can group them into oscillators (Atkinson et al. 2003; Elowitz and Leibler 2000; Stricker et al. 2008), mono-stable systems (Becskei and Serrano 2000), and bistable systems called toggle switches (Gardner et al. 2000). More recently, feedforward loops have also been fabricated (Bleris et al. 2011).

Oscillators. The creation of circuits whose protein concentrations oscillate periodically in time has been a major focus. In fact, the ability of creating an oscillator has the potential of shedding light into the mechanisms at the basis of natural clocks, such as circadian rhythms and the cell cycle. Oscillator designs can be divided into two types: loop oscillators (Elowitz and Leibler 2000), in which repression/activation interactions occur in a loop topology, or oscillators based on the interplay between an autocatalytic loop and negative feedback (Atkinson et al. 2003; Stricker et al. 2008) (see Fig. 1).

The design requirements of synthetic circuits are usually explored through models of varying detail, starting with the use of low-dimensional "toy models," which are composed of a set of nonlinear ordinary differential equations describing the rate of change of the circuit's proteins. These models allow application of a number of tools from dynamical systems theory to infer parameter or structural requirements for a desired behavior. After toy models are analyzed, larger-scale mechanistic models are constructed, which include all the intermediate species taking part in the biochemical reactions. These models can be
Synthetic Biology, Fig. 1 Early gene circuits that have been fabricated in bacteria *E. coli*: the negatively autoregulated gene (Becskei and Serrano 2000), the toggle switch (Gardner et al. 2000), the activator-repressor clock (Atkinson et al. 2003), and the repressilator (Elowitz and Leibler 2000)

either deterministic or stochastic. Simulation is usually required for the study of these more complicated models, and the Gillespie algorithm is often employed for stochastic simulations (Gillespie 1977).

As an example of a toy model and related analysis, consider the activator-repressor clock of Atkinson et al. (2003) shown in Fig. 1. This oscillator is composed of an activator A activating itself and a repressor B, which, in turn, represses the activator A. Both activation and repression occur through transcription regulation. Denoting in italics the concentration of species, a toy model of this clock can be written as

$$
\begin{aligned}
\dot{A} &= \frac{\beta_A (A/K_a)^n + \beta_{0,A}}{1 + (A/K_a)^n + (B/K_b)^m} - \gamma_A A, \\
\dot{B} &= \frac{\beta_B (A/K_a)^n + \beta_{0,B}}{1 + (A/K_a)^n} - \gamma_B B,
\end{aligned}
\tag{1}
$$

in which γ_A and γ_B represent protein decay (due to dilution and/or degradation). The functions $(\beta_A (A/K_a)^n + \beta_{0,A})/(1 + (A/K_a)^n + (B/K_b)^m)$ and $(\beta_B (A/K_a)^n + \beta_{0,B})/(1 + (A/K_a)^n)$ are called Hill functions and are the most commonly used models for transcription regulation (Alon 2007). The first Hill function in system (1) increases with A and decreases with B, while
Synthetic Biology, Fig. 2 Activator-repressor clock time trajectory

the second one increases with *A*, as expected since A is an activator and B is a repressor. The key mechanism by which this system displays sustained oscillations is a supercritical Hopf bifurcation with bifurcation parameter the relative timescale of the activator dynamics with respect to the repressor dynamics (Del Vecchio 2007). Specifically, as the activator dynamics become faster than the repressor dynamics, the system goes through a supercritical Hopf bifurcation and a stable periodic orbit appears (Fig. 2).

Mono-stable systems. The mono-stable system engineered through negative autoregulation was fabricated with the aim of understanding the role of negative feedback in attenuating biological noise. The results of Becskei and Serrano (2000) clearly showed that negative autoregulation can reduce intrinsic noise. Furthermore, the results of Austin et al. (2005) demonstrated that while low frequency noise is attenuated, noise at high frequency can be amplified by negative autoregulation in accordance with Bode's integral formula (Åström and Murray 2008).

Bistable systems. The toggle switch of Gardner et al. (2000) was the first bistable system constructed. It constitutes the simplest circuit with memory, in which the state of the system can be switched from one equilibrium (low, high) to the other (high, low) by external inputs. Once the system state is switched to one of these two equilibria, it will stay there unless another external perturbation is applied.

Feedforward loops. While the early circuits described so far were fabricated mainly to investigate design principles for limit cycles and for robustness, many more circuits after those have been fabricated with the aim of solving concrete engineering problems. As an example, the incoherent feedforward circuit of Bleris et al. (2011) was fabricated in bacteria *E. coli* with the aim of making protein production independent of DNA plasmid copy number. In fact, DNA copy number fluctuates stochastically with possibly large deviations from the nominal value. As a consequence, the concentration of proteins expressed from genes residing on a plasmid also fluctuates stochastically. In order to make protein concentration independent of an unknown DNA copy number, one could leverage principles for disturbance rejection such as integral control. While an explicit integral control action is particularly hard to implement through biological parts, incoherent feedforward loops are easier to implement and can accomplish the same disturbance rejection task. In these loops, the disturbance input affects the output through two branches, one in which the disturbance activates the output and a longer one in which the disturbance represses the output (Alon 2007). If these two branches are appropriately balanced, the steady-state value of the output will be practically independent of the disturbance input, leading to disturbance rejection to constant or slowly changing disturbances.

From Modules to Systems

One approach to creating systems that can accomplish sophisticated tasks is to assemble together simpler modules, such as those described in the previous section (Purnick and Weiss 2009). For example, the artificial tissue homeostasis circuit proposed by Miller et al. (2012) is composed of several interconnected modules, including an activator-repressor clock, a toggle switch, a couple of inverters, and an "and" gate. Control of tissue homeostasis refers to the ability of regulating a cell type to a constant level in a multicellular community. This ability is central in several diseases such as cancer and diabetes, in which tissue homeostasis is misregulated. The design proposed by Miller et al. (2012) illustrates how a synthetic biological circuit can be modularly created to accomplish this complicated regulation function.

Layered logic gates are often necessary in order to integrate multiple signals. Moon et al. (2012) have constructed an "and" gate that integrates more than two signals by cascading pairs of "and" gates. Of course, problems of latency become more relevant as the number of layers increases and methods to mitigate these effects are being developed.

An application that requires the integration of multiple signals is the cell-type classifier of Xie et al. (2011). Here, a synthetic gene circuit is created that integrates sensory information from a number of molecular markers to determine whether a cell is in a specific state, that is, cancer, and, in such a case, produces a protein output triggering cell death. The design of this circuit is based on the composition of three key modules. Specifically, a double inversion module senses high levels of a molecular marker, a single inversion module senses low levels of a molecular marker, and a logical "and" module finally integrates the outputs of the other two modules to produce the output protein.

Finally, biofuels are another high-impact application of synthetic biology (Peralta-Yahya et al. 2012). Metabolic engineering has been employed for a long time in order to engineer microbes to produce advanced biofuels with similar properties to petroleum-based fuels. One challenge in using microbes (or other living organisms) to convert feedstock into biofuel is that of overcoming the endogenous cell regulation to achieve sufficiently high yields such that advanced biofuels are economically advantageous. Specifically, engineered pathways are optimized on the basis of nominal operating conditions, but these conditions often change when microbes are in bioreactors. To mitigate this problem, synthetic gene circuits have been designed to sense the metabolic status of the host and regulate key points in the metabolic pathway to optimize yield (Zhang et al. 2012).

Main System-Level Challenges to Design

One major challenge in synthetic biology is the ability of going from simple modules to larger sophisticated systems (Purnick and Weiss 2009). Problems in advancing in this direction can be divided into two categories: "hardware" problems and system-level problems. Hardware problems include issues such as the availability of enough orthogonal parts to allow scaling up the size of synthetic circuits. We do not expand on this here and instead focus on system-level problems. These include issues such as *context dependence* (Cardinale and Arkin 2012), that is, the fact that modules behave in a poorly predictable way once interacting together in the cell environment. This is a major obstacle to creating larger circuits that behave predictably.

Problems of context dependence can be further divided into three qualitatively different types: (a) inter-modular interactions, (b) interactions of synthetic circuits with the cell machinery, (c) perturbations in the external environment. We analyze each of them separately.

(a) When modules are connected to each other to create larger systems, a protein in an upstream module is used as an "input" to

a downstream module. This fact creates a "loading" on the upstream system due to the fact that the output protein cannot take part in the upstream module reactions whenever it is taking part in the downstream module reactions. As a consequence, the behavior of the upstream system changes compared to when the system functions in isolation (Del Vecchio et al. 2008; Saez-Rodriguez et al. 2004). These loading effects have been called retroactivity to extend the notion of loading and impedance to biomolecular systems. Accordingly, solutions to mitigate this problem are being investigated (Franco et al. 2011; Jayanthi and Del Vecchio 2011; Mishra et al. 2013).

(b) Ideally, the cell should function as a "chassis" for synthetic biology circuits. In practice, this is not the case because the endogenous circuitry interacts with synthetic circuits even when parts that are orthogonal to the endogenous systems are employed. A major example of this interaction is the depletion of cellular resources, such as ATP, RNA polymerase, and ribosomes, which are required for the operation of synthetic circuits. This depletion reduces cell fitness, with deleterious consequences also for synthetic circuits, a phenomenon called "metabolic burden" (Bentley et al. 1990). A more subtle phenomenon than purely reducing cell fitness is that synthetic circuits compete with each other for the same resources. This fact creates implicit and unwanted coupling among circuits with unpredictable consequences. Approaches to mitigate these problems are under investigation. One direction is the use of orthogonal RNA polymerase and ribosomes (Wenlin and Chin 2009; Rackham and Chin 2005). A completely different, but complementary, direction is that of establishing implementable design principles that allow circuits to function robustly despite fluctuations in the resources they use.

(c) The external environment where a cell operates has a number of physical attributes, which may also be subject to perturba-

tions. These physical attributes include temperature, acidity, nutrients' level, etc. Perturbations in these attributes often lead to poor cell fitness or to nonstandard growth conditions, ultimately leading to synthetic circuits malfunctions.

Summary and Future Directions

The future of synthetic biology highly depends on the ability of scaling up the complexity of design to create more sophisticated functions. While a number of issues, such as the availability of enough orthogonal parts, can be successfully addressed by (nontrivial) fabrication of new parts, issues such as context dependence require a system-level dynamic understanding of circuits and their interactions. Here is where control and dynamical systems theory could greatly contribute. Control theory has proven critical to reason about and engineer robustness in a number of concrete applications including aerospace and automotive systems, robotics and intelligent machines, manufacturing chains, electrical, power, and information networks. Similarly, control theory could enable the understanding of principles that ensure robust behavior of synthetic circuits once interacting with each other in the cell environment, leading to the ultimate progress of synthetic biology.

A number of challenges need to be addressed for the successful application of control and dynamical systems theory to synthetic biology. The behavior of synthetic circuits is highly nonlinear and, as a consequence, control theoretic tools designed for understanding robustness in linear systems are not directly applicable. Understanding how to exploit the rich structure of biomolecular circuits to quantitatively reason about robustness to interconnections, competition for shared resources, and fluctuations of temperature and nutrients is likely to have a major impact. Even with this understanding, however, the question of how to implement robust designs with the currently available biomolecular mechanisms must be addressed. Stochasticity is another major problem since the behavior of synthetic circuits is intrin-

sically noisy. Unfortunately, the availability of analytical tools that allow quantification of how perturbations and uncertainty propagate through a nonlinear stochastic system is still limited, and designers often resort to stochastic simulation. Finally, the values of the salient parameters of the available parts are poorly known. Physical attributes such as binding affinities, ribosome binding site strengths, promoter strengths, etc. are only known within very coarse bounds. These bounds are also usually determined based on a specific organism and in specific growth conditions, which may be different from the ones in which the circuit is ultimately running. Hence, a central question is how to design and implement a system such that the prescribed behavior is robust to all sources of perturbations described above within a large range of possible parameter values.

System Identification Software

Brett Ninness
School of Electrical and Computer Engineering, University of Newcastle, Newcastle, Australia

Abstract

This contribution discusses various aspects important to software for system identification. Essential functionality for existing practice and the algorithmic fundamentals this relies on are considered together with a brief discussion of additional commonly useful support tools. Since software is intimately tied to the hardware that it runs on, a discussion on this topic follows with an emphasis on considering how future system identification software developments might best align with clear current and future trends in computer architecture developments.

Keywords

System identification; Computer-aided design; Parameter estimation; Software

Introduction

Fundamental to the practice of system identification is the employment of appropriate software to compute system estimates and evaluate their properties. One option is for the user to code the necessary routines themselves in their computer language of choice. For simple situations, such as least-squares estimation with a linearly parametrized model, this approach is feasible.

However, it quickly becomes onerous and time consuming as one moves even slightly beyond this simple example. In response to this, researchers have developed a number of software packages designed to accommodate classes of data formats, model structures, and estimation methods.

The purpose of this contribution is to profile the support that available system identification software provides, the underlying foundations on which this software depends, and the future capabilities that may be expected due to trends in desktop and portable computer capacity.

The material to follow depends on explanations, definitions, and background presented in ▶ System Identification: An Overview, by Ljung, which should be read in conjunction with this contribution.

Essential Functionality

The essence of system identification software packages is that they implement an identification method $\mathcal{I}$ as defined in ▶ System Identification: An Overview.

Typically, this involves taking a model structure specification $\mathcal{M}(\theta)$ together with N observed data points Z_N and translating that to a cost function $V_N(\theta)$ for which a minimizer

$$\hat{\theta} \triangleq \underset{\theta \in D_{\mathcal{M}}}{\arg\min} \, V_N(\theta) \qquad (1)$$

is then computed in order to deliver a system estimate $\mathcal{M}(\hat{\theta})$.

While the details of these fundamental operations vary according to the chosen model structure and method, there are some shared aspects. To pick a starting point, subspace-based estimation methods (▶ Subspace Techniques in System

Identification) have been one of the most significant developments in the near history of system identification, and they fundamentally involve a first stage of setting up and solving the optimization problem

$$\hat{\beta} = \arg\min_{\beta} \|Y - \Phi\beta\|_F^2, \qquad (2)$$

where Y, Φ are data-dependent matrices, β is a θ- dependent matrix, and $\|\cdot\|_F$ is the Frobenius norm, which, for an $m \times n$ matrix A, is defined as

$$\|A\|_F = \sqrt{\sum_{i=1}^{m}\sum_{j=1}^{n}|a_{ij}|^2}. \qquad (3)$$

This is a classic least-squares optimization problem, which also arises in other system identification contexts, particularly when the prediction $\hat{y}(t \mid \theta)$ is a linear function of θ.

As is well known Golub and Loan (1989), the minimizer $\hat{\beta}$ satisfies the "normal equations"

$$(\Phi^T\Phi)\hat{\beta} = \Phi^T Y, \qquad (4)$$

and if $\Phi^T\Phi$ is invertible, this allows for a closed-form solution

$$\hat{\beta} = (\Phi^T\Phi)^{-1}\Phi^T Y. \qquad (5)$$

While formally correct, no system identification software packages would compute $\hat{\beta}$ in this manner since it is computationally inefficient and sensitive to numerical rounding errors.

Drawing on decades of study on this topic in the numerical computations literature (Golub and Loan 1989), system identification software packages rely on the QR factorization

$$\Phi = QR = [Q_1 \mid Q_2]\begin{bmatrix} R_1 \\ 0 \end{bmatrix}, \qquad (6)$$

where Q is square and satisfies $Q^T Q = I$ (the identity matrix) and R contains the upper triangular square and invertible block R_1. This decomposition of Φ allows the normal Eq. (4) to be re-expressed as

$$R_1\hat{\beta} = Q_1^T Y. \qquad (7)$$

Since R_1 is upper triangular, the solution $\hat{\beta}$ may then be found by elementary and numerically robust backward substitution (Golub and Loan 1989).

The importance of efficient and accurate solution of normal equations to any system identification software is not limited to these subspace or linearly parametrized cases. For instance, the very general class of prediction error methods encompassed by the formulation (1) involves a cost $V_N(\theta)$ that depends on the vector

$$E(\theta) \triangleq [\varepsilon(t_1, \theta), \cdots, \varepsilon(t_N, \theta)]^T \qquad (8)$$

of differences between the observed data and the response of a model parametrized by θ. In the case of time-domain data, the elements of (8) are defined by

$$\varepsilon(t, \theta) \triangleq y(t) - \hat{y}(t \mid \theta). \qquad (9)$$

In this general situation, it is most commonly the case that no closed-form solution for the optimization problem (1) exists.

The strategy then taken by most system identification software packages is to employ a gradient-based search for a minimizer. These methods are motivated by the use of a linear approximation of $E(\theta)$ about a current putative minimizer θ_k according to

$$E(\theta) \approx E(\theta_k) + J(\theta_k)(\theta - \theta_k), \qquad (10)$$

where $J(\theta_k)$ denotes the Jacobian matrix

$$J(\theta_k) \triangleq \left.\frac{\partial E(\theta)}{\partial \theta}\right|_{\theta=\theta_k}. \qquad (11)$$

In the very common situation where $V_N(\theta)$ is a quadratic function of $E(\theta)$, this implies the associated approximation

$$V_N(\theta) = \text{Trace}\{E^T(\theta)E(\theta)\}$$
$$= \|E\|_F^2 \approx \|E(\theta_k) + J(\theta_k)(\theta - \theta_k)\|_F^2. \qquad (12)$$

S

Via this reasoning, computation of an appropriate "search direction" $p = \theta - \theta_k$ again involves the efficient solution of a linear least-squares problem of the form (2), namely,

$$p = \arg\min_p \|E(\theta_k) + J(\theta_k)\, p\|_F^2. \qquad (13)$$

More generally, system identification software packages extend this rationale and solve (1) by generating a sequence of iterations $\{\theta_k\}$, which are refined according to

$$\theta_{k+1} = \theta_k + \mu\, p, \qquad (14)$$

where μ is a step length that at each iteration k may be altered until a cost decrease

$$V_N(\theta_{k+1}) < V_N(\theta_k) \qquad (15)$$

is achieved and the search direction p again involves the solution of normal equations

$$\left[J(\theta_k)^T J(\theta_k) + \lambda I \right] p = -J(\theta_k)^T E(\theta_k). \qquad (16)$$

The choice $\lambda > 0$ implies what is called a Levenberg–Marquardt method, while $\lambda = 0$ leads to a so-called Gauss–Newton update strategy, and there are further variants such as "trust region" methods that are typically offered as options.

Via (16) we see that again system identification software comes to fundamentally depend on underpinning numerical linear algebra, in this case, again via the QR decomposition.

Another decomposition, the singular value decomposition (SVD), also has a significant role to play, particularly with respect to subspace-based methods where it is essential to the extraction of an estimated system parametrization $\hat{\theta}$ from $\hat{\beta}$ referred to in (2).

In addition to matrix decompositions, other system identification methods depend on many other even more fundamental linear algebra tools such as basic matrix/vector operations, matrix inversion, and eigen-decomposition. Because of this dependence, most (Ljung 2012; Kollár et al. 2006; Young and Taylor 2012; Garnier et al.

2012; Ninness et al. 2013) but not all (Hjalmarsson and Sjöberg 2012) currently available system identification software packages are built upon the MathWorks MATLAB (originally short for "matrix laboratory") package, which provides an efficient interface to the widely accepted standard numerical linear algebra libraries LAPACK and EISPACK. For example, solving (2) efficiently and robustly via QR decomposition and back-substitution of (7) is achieved transparently using the MATLAB backslash operator with the simple command: `beta = Phi\Y`.

Additional Functionality and the Decision-Making Process

As emphasized in ▶ System Identification: An Overview, the provision of an estimated model is typically an iterative process (illustrated diagrammatically in Fig. 4 of ▶ System Identification: An Overview) of which just one component is the implementation of an identification method $\mathcal{I}$ to deliver a system estimate $\mathcal{M}(\hat{\theta})$.

In addition to this "essential functionality," system identification software must also provide tools and a logistical support for the decision-making process of assessing $\mathcal{M}(\hat{\theta})$ and, based on this, perhaps altering aspects such as the choice of model structure $\mathcal{M}$, the experiment design $\mathcal{X}$, or indeed the identification method $\mathcal{I}$.

To support this, system identification software packages may offer further capabilities such as:

1. Nonparametric estimation methods that deliver estimates of linear system frequency response without involving a parametrized model structure $\mathcal{M}(\theta)$ and hence not involving (1)
2. Data preprocessing tools, such as to remove trends and to frequency selectively prefilter data before use
3. Visualization tools to display and compare the time- and frequency-domain response of estimated models
4. Model validation tools to determine if estimated models can be falsified by observed data

5. Model accuracy measures that deliver statistical confidence bounds on estimated parameters

6. Additional data processing tools such as Kalman filtering and smoothing routines and sequential Monte Carlo (particle filter) routines that are used to compute $V_N(\theta)$ but have many other applications

7. Graphical user interface (GUI) support in order to aid organization of the various aspects of data preprocessing, model structure selection, algorithm selection, estimate computation, model validation, and model visualization

8. The employment of symbolic computation capabilities to aid complex model structure specification and preprocessing for efficient numerical implementation (Hjalmarsson and Sjöberg 2012)

Note that with the exception of this last point (8), the computations associated with this additional functionality again depend fundamentally on efficient numerical linear algebra software.

Computing Platforms

Currently available system identification software packages are designed for standard desktop computing environments, and as such their capabilities are intimately tied to those of the central processing unit (CPU), memory, and other architectural features of this hardware.

For instance, the linear algebra underpinnings just discussed are typically implemented in serially coded form, and hence bus bandwidth, together with memory and CPU speed, will be the fundamental factor affecting software performance. Taking CPU speed as an example, the evolution of clock speed for the very commonly used Intel architecture CPUs is shown as the red curve in Fig. 1 and, as can be seen, has largely plateaued over the last decade after two orders of magnitude growth in the decade preceding it.

As a result, and roughly speaking, system estimates that took a minute to compute in the early 1990s took under a second to compute in the early part of this century, but are essentially no faster to compute now, a further decade later.

As a result, while system identification software has continued to grow in sophistication, in areas that involve high computational burdens, such as estimation of complex and high-dimensional model structures, or the implementation of compute intensive algorithms, the capability of system identification software has been hardware limited for some time.

At the same time, as the blue line in Fig. 1 illustrates, Moore's law continues to hold, and

System Identification Software, Fig. 1 Trends in desktop CPU capacity taking Intel as an example. Serial throughput speeds have long plateaued, but transistor density continues to grow, which delivers growing multiple cores
transistor densities continue to increase. While this is delivering no greater serial CPU speed, it is delivering multiple CPU core availability. Future advances in system identification software capability will therefore need to exploit the potential for parallel computation.

Indeed, in current MATLAB, the fundamental numerical linear algebra routines previously mentioned such as QR-based solution of normal equations, eigenvalue, and SVD decompositions will all automatically execute on multiple computational threads on multicore-enabled machines. Expanding this to take advantage of even higher levels of parallelism is the subject of current research.

While these developments will deliver performance enhancements for existing system identification methods, they will also open up the possibility for new tools to be added to system identification software suites.

For example, in addition to the existing subspace, prediction error, and maximum likelihood methods just mentioned, there is another important estimation approach that does not involve the solution of an optimization problem such as (1) or (2) and for which there is always a closed-form expression for the parameter estimate. It is the conditional mean estimate

$$\hat{\theta} = \mathbf{E}\{\theta \mid Y\}, \tag{17}$$

which is a Bayesian approach that depends on the calculation of the posterior density of the parameters θ given the data Y according to

$$p(\theta \mid Y) = \frac{p(Y \mid \theta)p(\theta)}{p(Y)}, \tag{18}$$

where $p(\theta)$ is a prior that allows for incorporation of user knowledge (before observing the data) and $p(Y \mid \theta)$ is the usual data likelihood.

Not only does this estimate have an explicit formulation; it is also the minimum mean square error estimate in that for any other estimate $\hat{\beta} = f(Y)$ computed as any other measurable function f of the data Y, it holds that

$$\mathbf{E}\left\{\|\theta - \hat{\theta}\|^2\right\} \leq \mathbf{E}\left\{\|\theta - \hat{\beta}\|^2\right\}. \tag{19}$$

In this sense, the conditional mean (17) is the most accurate estimate. Furthermore, quantifications of estimation accuracy may be directly obtained via the marginal densities $p(\theta_i \mid Y)$ of individual parameter vector values θ_i.

Nevertheless, it is currently not widely used. There are no doubt philosophical reasons for this stemming from the well-known debate between frequentist and Bayesian perspectives on inference (Efron 2013).

Another key reason is that it is difficult to compute. It requires the evaluation of a multidimensional integral,

$$\mathbf{E}\{\theta \mid Y\} = \int \int \cdots \int \theta \, p(\theta \mid \mathcal{Y}_N) \, d\theta_1 \cdots d\theta_n \tag{20}$$

as does the computation of the marginal densities

$$p(\theta_i \mid \mathcal{Y}_N) = \int \cdots \int p(\theta \mid \mathcal{Y}_N) \, d\theta_1$$
$$\cdots d\theta_{i-1} d\theta_{i+1} \cdots d\theta_n. \tag{21}$$

Evaluating these quantities requires adding fundamentally new capability beyond efficient linear algebra support to system identification software. It involves adding capability for numerical integration.

Integration in one dimension is straightforward. The well-known and used Simpson's rule is remarkably efficient in that the relationship between the computational error and the number of grid points m obeys

$$\text{Error} = O(m^{-4}) \tag{22}$$

so that every order of magnitude increase in m delivers four extra digits of precision. However, (20) is an $n_\theta = \dim\{\theta\}$ dimensional integral, and m grid points on each of n_θ axes imply

$$M = m^{n_\theta} \tag{23}$$

function evaluations. This can blow up quite quickly, as illustrated in Fig. 2 for the case of only modest $m = 30$ grid points and with respect to the very simple problem of estimating a
System Identification Software, Fig. 2 Increase in number of function evaluations M required for Simpson's rule integration with $m = 30$ grid points on each parameter axis associated with linear output-error models of increasing order. Note that accounting for both numerator and denominator parameters, $n_\theta = 2 \times$ model order $+ 1$

straightforward linear output-error model of increasing order.

On a serial CPU platform, there is an upper limit of time available to wait for a result and hence an upper limit M of function evaluations that are tolerable. Viewed as a function of this, the accuracy of simple Simpson's rule methods is

$$\text{Error} = O(M^{-4/n_\theta}), \qquad (24)$$

which is not attractive as model complexity and hence n_θ grows.

A further and vitally important problem is that it will generally not be clear where to allocate the m grid points on each axis since the support of the posterior $p(\theta \mid Y)$ is not readily known. Indeed, a main point of computing the multidimensional integrals associated with the marginals (21) is to determine this support.

A strategy to address these difficulties is based on the strong law of large numbers (SLLN). Namely, if random draws $x^i \sim p(x)$ from a density $p(x)$ can be obtained, then sample averages of functions of them converge with probability one to the ensemble average expectation, which is an integral:

$$\frac{1}{M} \sum_{i=1}^{M} f(x^i) \xrightarrow{\text{w.p.1}} \mathbf{E}\left\{f(x^i)\right\} = \int f(x)p(x)\,\mathrm{d}x. \qquad (25)$$

This principle may then be used as a "randomized" method to compute an estimate $\hat{I}_M$ of an integral I; viz.,

$$I = \int f(x)p(x)\,\mathrm{d}x \approx \hat{I}_M \triangleq \frac{1}{M}\sum_{i=1}^{M} f(x^i). \qquad (26)$$

Furthermore, if the x^i are independent draws, then

$$\text{Var}\{\hat{I}_M\} = \frac{1}{M^2}\sum_{i=1}^{M}\text{Var}\{f(x^i)\} = \frac{1}{M}\text{Var}\{f(x)\}, \qquad (27)$$

and hence the absolute error in integral evaluation is

$$O(|I - \hat{I}_M|) \approx O(M^{-1/2}). \qquad (28)$$

The vital point is that as opposed to (24), this error is *independent* of the dimension of x and hence *independent* of the dimension of the integral I. Furthermore, the grid points are the realizations $\{x^i\}$, which naturally will lie within the support of the integrand $f(x)p(x)$ and do not need to be otherwise designed.

Of course, this depends on a means to draw samples from an arbitrary density $p(\cdot)$ of interest, but simple methods such as the Metropolis–Hastings methods and "slice sampler" exist to achieve this Mackay (2003).

Importantly too, these randomized methods are ideally suited to exploiting the growing availability of desktop multicore computing platforms. Generating M realizations to form the integral approximation $\hat{I}_M$ in (26) may be achieved in one-tenth the time simply by running ten independently initialized random number generators in parallel, each generating one $M/10$ length realization. The method (26) is thus (in principal) trivial to parallelize.

Furthermore, much greater parallelization and hence also speedup may be achieved by employing the "graphics processing units" (GPUs) in desktop computers. These GPUs are inexpensive because they service a high volume

S

consumer demand for interactive gaming, which requires high-speed numerical computation for 3D-projected graphics. As such these GPUs have evolved to provide hundreds of parallel processing cores, each clocked in the gigahertz range.

To give an impression of the computational capability of GPU-based platforms, the single-precision giga-FLOPS (floating-point operations per second) performance history for NVIDIA brand GPUs and Intel architecture processors designed for desktop applications is profiled in Fig. 3.

This shows theoretical performance, assuming all cores may be fully utilized constantly. In reality, this is never possible due to communication and architecture restrictions. For example, GPU architectures are based on an SIMD (single instruction, multiple data) design, so at any one time many cores must execute the identical instruction, but may do so on different data. Analysis of these and other aspects relevant for system identification software implementation requires detailed study (Lee et al. 2010).

The fact that desktop hardware architectures have and will continue to offer more but not faster processing cores may be exploited in system identification software beyond this Bayesian setting. For example, the last decade has seen great interest in delivering estimation methods for an increasingly broad range of nonlinear model structures, a quite general version of which can be expressed in the nonlinear state–space form

$$x(t+1) \sim p(x(t+1) \mid x(t), \theta) \qquad (29)$$

$$y(t) \sim p(y(t) \mid x(t), \theta). \qquad (30)$$

In principle, there is no reason why this cannot be straightforwardly addressed by the usual maximum likelihood approach of forming the likelihood

$$p(Y_N \mid \theta) = \prod_{t=1}^{N} p(y(t) \mid Y_{t-1}, \theta),$$

$$Y_t = \{y(1), \cdots, y(t)\} \qquad (31)$$

and then using this as the cost function $V_N(\theta)$ in (1) and then proceeding with the usual gradient-based search. Indeed, there exist explicit formulae for computing the predictive densities $p(y(t) \mid Y_{t-1}, \theta)$ required in (31). Namely, the coupled measurement update

$$p(x(t) \mid Y_t, \theta) = \frac{p(y(t) \mid x(t), \theta)p(x(t) \mid Y_{t-1}, \theta)}{p(y(t) \mid Y_{t-1}, \theta)}$$

$$p(y(t) \mid Y_{t-1}, \theta) =$$
$$\int p(y(t) \mid x(t), \theta)p(x(t) \mid Y_{t-1}) \, \mathrm{d}x(t)$$

and time update

$$p(x(t+1) \mid Y_t, \theta) =$$
$$\int p(x(t+1) \mid x(t), \theta) \, p(x(t) \mid Y(t), \theta) \, \mathrm{d}x(t) \qquad (32)$$

equations.

However, again we are faced with the problem of numerically evaluating multidimensional integrals. The integral dimension this time is that of the state vector $x(t)$, which may be less than that of the parameter vector θ just discussed, but $2N$ of these integrals needs to be evaluated in order to compute the likelihood (31), and this needs to be redone for each step of any associated gradient-based search.

Again, a randomized algorithm approach based on the SLLN could be considered as a way forward in system identification software development. Indeed, sequential Monte Carlo (SMC) algorithms (aka particle filtering) (Doucet and Johansen 2011) have been specifically developed to compute the above integrals involved in the time and measurement update, and there has been recent work (Schön et al. 2011; Andrieu et al. 2010) on employing this to develop software for the estimation of the general nonlinear model (29) and (30).

The resulting algorithms are computationally intensive, to the point where implementation on serial CPU architectures means they are limited to deployment on nonlinear model structures of very low state dimension. However, again

System Identification Software, Fig. 3 Historical trend of theoretical single-precision giga- FLOPS performance of commodity NVIDIA brand GPUs versus Intel architecture CPUs designed for desktop computing
because the SLLN is at the heart of the methods, and averaging over one long run on a serial machine is numerically equivalent (but potentially much faster) to averaging over multiple shorter runs computed in parallel, there is scope for future system identification software to employ these approaches.

Examples of Available System Identification Software

With the features of current and perhaps future system identification software packages profiled, it may be useful to make specific mention of particular system identification software packages that have been under active development for a substantial period of time. These include the following commercially available packages:

1. The *MathWorks System Identification Toolbox* (Ljung 2012), which is arguably the most mature and comprehensive system identification software available
2. The *GAMAX Frequency Domain System Identification Toolbox* (Kollár et al. 2006), which specializes in estimation of models based on measurements in the frequency domain

3. The *Adaptx* software (Larimore 2000) specializing in the estimation of state–space models using subspace-based methods

Noncommercial and freely available system identification software packages that are relevant include:

1. The "computer-aided program for time-series analysis and identification of noisy systems" (CAPTAIN) toolbox (Young and Taylor 2012), which provides a platform supporting the "refined instrumental variable" (RIV) algorithm for linear system estimation;
2. The "continuous-time system identification" (CONTSID) toolbox (Garnier et al. 2012), which specializes in the estimation of continuous-time models
3. The "interactive software tool for system identification education" (ITSIE) toolbox (Guzmán et al. 2012), which has an emphasis on education and training in system identification principles
4. The "University of Newcastle identification toolbox" (UNIT) software (Ninness et al. 2013) that is designed as an open platform for researchers to evaluate the performance of new methods relative to established ones

Summary and Future Directions

A case can be mounted that at its heart, system identification is about the design of software and the understanding of the results provided by it. Certainly, the field has been built on decades of deep theoretical contributions, but this has been very practically focused either on delivering new algorithms that may be directly implemented or on better understanding the performance of existing algorithms.

Efficient numerical linear algebra routines have traditionally been the foundation of the resulting proven and effective system identification methods and software to date, and these have scaled in effectiveness as desktop computing clock speeds have scaled.

However, the recent past and the foreseeable future see CPU speed as static and with an increasing number of available processor cores. Delivering greater system identification capacity will require the development of methods whose software implementations can harness this growing availability of multiple processor cores.

Abstract

System identification has been developed, by and large, following the classical parametric approach. In this entry we discuss how regularization theory can be employed to tackle the system identification problem from a nonparametric (or semi-parametric) point of view. Both regularization for smoothness and regularization for sparseness are discussed, as flexible means to face the bias/variance dilemma and to perform model selection. These techniques have also advantages from the computational point of view, leading sometimes to convex optimization problems.

Keywords

Kernel methods; Nonparametric methods; Optimization; Sparse Bayesian learning; Sparsity

Introduction

System identification is concerned with automatic model building from measured data. Under this unifying umbrella, this field spans a rather broad spectrum of topics, considering different model classes (linear, hybrid, nonlinear, continuous, and discrete time) as well as a variety of methodologies and algorithms, bringing together in a nontrivial way concepts from classical statistics, machine learning, and dynamical systems.

Even though considerable effort has been devoted to specific areas, such as parametric methods for linear system identification which are by now well developed (see the introductory article ▶ System Identification: An Overview), it is fair to say that modeling still is, by far, the most time-consuming and costly step in advanced process control applications. As such, the demand for fast and reliable automated procedures for system identification makes this exciting field still a very active and lively one.

Suffices here to recall that, following this classic parametric maximum likelihood (ML)/prediction error (PE) framework, the candidate models are described using a finite number of parameters $\theta \in \mathbb{R}^n$. After the model classes have been specified, the following two steps have to be undertaken:

(i) Estimate the model complexity $\hat{n}$.
(ii) Find the estimator $\hat{\theta} \in \mathbb{R}^{\hat{n}}$ minimizing a cost function $J(\theta)$, e.g., the prediction error or (minus) the log-likelihood.

Both of these steps are critical, yet for different reasons: step (ii) boils down to an optimization problem which, in general, is non-convex and as such it is very hard to guarantee that a global minimum is achieved. The regularization techniques discussed in this entry sometimes allow to reformulate the identification problem as a convex program, thus solving the issue of local minima.

In addition fixing the system complexity equal to the "true" one is a rather unrealistic assumption and in practice the complexity n has to be estimated as per step (i). In practice there is never a "true" model, certainly not in the model class considered. The problem of statistical modeling is first of all an approximation problem; one seeks for an approximate description of "reality" which is at the same time simple enough to be learned with the available data and also accurate enough for the purpose at hand. On this issue see also the section "Trade-off Between Bias and Variance" in ▶ System Identification: An Overview. This has nontrivial implications, chiefly the facts that classical order selection criteria are based on asymptotic arguments and that the statistical properties of estimators $\hat{\theta}$ after model selection, called post-model-selection estimators (PMSEs), are in general difficult to study (Leeb and Pötscher 2005) and may lead to undesirable behavior. Experimental evidence shows

S

that this is not only a theoretical problem but also a practical one (Pillonetto et al. 2011; Chen et al. 2012). On top of this statistical aspect, there is also a computational one. In fact the model selection step, which includes as special cases also variable selection and structure selection, may lead to computationally intractable combinatorial problems. Two simple examples which reveal the combinatorial explosion of candidate models are the following: (a) *Variable selection*: consider a high-dimensional time series (MIMO) where not all inputs/outputs are relevant and one would like to select k out of m available input signals where k is not known and needs to be inferred from data; (see, e.g., Banbura et al. (2010) and Chiuso and Pillonetto (2012)), and (b) *structure selection*: consider all autoregressive models of maximal lag p with only $p_0 < p$ nonzero coefficients and one would like to estimate how many (p_0) and which coefficients are nonzero. The same combinatorial problem arises in hybrid system identification (e.g., switching ARX models). Given that enumeration of all possible models is essentially impossible due the combinatorial explosion of candidates, selection could be performed using greedy approaches from multivariate statistics, such as stepwise methods (Hocking 1976).

The system identification community, inspired by work in statistics (Tibshirani 1996; Mackay 1994), machine learning (Rasmussen and Williams 2006; Tipping 2001; Bach et al. 2004), and signal processing (Donoho 2006; Wipf et al. 2011), has recently developed and adapted methods based on regularization to jointly perform model selection and estimation in a computationally efficient and statistically robust manner. Different regularization strategies have been employed which can be classified in two main classes: regularization induced by so-called smoothness priors (aka Tikhonov regularization; see Kitagawa and Gersh (1984) and Doan et al. (1984) for early references in the field of dynamical systems) and regularization for selection. This latter is usually achieved by convex relaxation of the ℓ_0 quasinorm (such as ℓ_1 norm and variations thereof such as sum of norms, nuclear norm, etc.) or other non-

convex sparsity-inducing penalties which can be conveniently derived in a Bayesian framework, aka sparse Bayesian learning (SBL) (Mackay 1994; Tipping 2001; Wipf et al. 2011).

The purpose of this entry is to guide the reader through the most interesting and promising results on this topic as well as areas of active research; of course this subjective view only reflects the author's opinion, and of course different authors could have offered a different perspective.

While, as mentioned above, system identification studies various classes of models (ranging from linear to general "nonlinear" models), in this entry, we shall restrict our attention to specific ones, namely, linear and hybrid dynamical systems. The field of nonlinear system identification is so vast (a quote sometimes attributed to S. Ulam has it that the study of nonlinear systems is a sort of "non-elephant zoology") that even though it has largely benefitted from the use of regularization, it cannot be addressed within the limited space of this contribution. The reader is referred to the Encyclopedia chapters ▶ Nonlinear System Identification: An Overview of Common Approaches and ▶ Nonlinear System Identification Using Particle Filters for more details on nonlinear model identification.

System Identification

Let $u_t \in \mathbb{R}^m$, $y_t \in \mathbb{R}^p$ be, respectively, the measured *input* and *output* signals in a dynamical system; the purpose of system identification is to find, from a finite collection of input-output data $\{u_t, y_t\}_{t \in [1,N]}$, a "good" dynamical model which describes the phenomenon under observation. The candidate model will be searched for within a so-called "model set" denoted by $\mathcal{M}$. This set can be described in parametric form (see, e.g., Eq. (3) in ▶ System Identification: An Overview) or in a nonparametric form. In this entry we shall use the symbol $\mathcal{M}_n(\theta)$ for parametric model classes where the subscript n denotes the model complexity, i.e., the number of free parameters.

Linear Models

The first part of the entry will address identification of linear models, i.e., models described by a convolution

$$y_t = \sum_{k=1}^{\infty} g_{t-k}u_k + \sum_{k=0}^{\infty} h_{t-k}e_k \quad t \in \mathbb{Z} \quad (1)$$

where g and h are the so-called impulse responses of the system and $\{e_t\}_{t\in\mathbb{Z}}$ is a zero-mean white noise process which under suitable assumptions is the one-step-ahead prediction error; a convenient description of the linear system (1) is given in terms of the transfer functions

$$G(q) := \sum_{k=1}^{\infty} g_k q^{-k} \quad H(q) := \sum_{k=0}^{\infty} h_k q^{-k}$$

The linear model (1) naturally yields an "optimal" (in the mean square sense) output predictor which shall be denoted later on by $\hat{y}_{t|t-1}$. As mentioned above, under suitable assumptions, the noise e_t in (1) is the so-called *innovation* process $e_t = y_t - \hat{y}_{t|t-1}$. See also Eq. (8) in ▶ System Identification: An Overview.

When g and h are described in a parametric form, we shall use the notation $g_k(\theta), h_k(\theta)$, and, likewise, $G(q,\theta), H(q,\theta)$, and $\hat{y}_{t|t-1}(\theta)$.

Example 7 Consider the so-called "output-error" model, i.e., assume $H(q) = 1$. An example of *parametric* model class is obtained restricting $G(q,\theta)$ to be a rational function

$$G(q,\theta) = K \prod_{i=1}^{n} \frac{q - z_i}{q - p_i}$$

where $\theta := [K, p_1, z_1, \ldots, p_n, z_n]$ is the parameter vector. Note that the parameter vector θ may subjected to constraints $\theta \in \Theta$, e.g., enforcing that the system be bounded input, bounded output (BIBO) stable ($|p_i| < 1$) or that the impulse response be real ($K \in \mathbb{R}$ and poles p_i and zeros z_i appear in complex conjugate pairs).

An example of *nonparametric* model is obtained, e.g., postulating that g_k is a realization of a Gaussian process (Rasmussen and Williams 2006) with zero mean and a certain covariance function $R(t,s) = \text{cov}(g_t, g_s)$. For instance, the choice $R(t,s) = \lambda^t \delta_{t-s}$, where $|\lambda| < 1$ and δ_k is the Kronecker symbol, postulates that the g_t and g_s are uncorrelated for $t \neq s$ and that the variance of g_t decays exponentially in t; this latter condition ensures that each realization g_k, $k > 0$, is BIBO stable with probability one. The exponential decay of g_t guarantees that, to any practical purpose, it can be considered zero for $t > T$ for a suitably large T. This allows to approximate the OE model with a "long" *finite impulse response* (FIR) model

$$G(q) = \sum_{k=1}^{T} g_k z^{-k} \quad (2)$$

where g_k, $k = 1, \ldots, T$, is modeled as a zero-mean Gaussian vector with covariance Σ, with elements $[\Sigma]_{ts} = R(t,s)$.

Remark 1 Note that the model (2), which has been obtained from truncation of a nonparametric model, could in principle be thought as a parametric model in which the parameter vector θ contains all the entries of g_k, $k = 1, \ldots, T$. Yet the truncation index T may have to be large even for relatively "simple" impulse responses; for instance, $\{g_k(\theta)\}_{k\in\mathbb{Z}^+}$ may be a simple decaying exponential, $g_k(\theta) = \alpha\rho^k$, which is described by two parameters (amplitude and decay rate), yet if $|\rho| \simeq 1$, the truncation index T needs to be large (ideally $T \to \infty$) to obtain sensible results (e.g., with low bias). Therefore, the number of parameters $T(m \times p)$ may be larger (and in fact much larger) than the available number of data points N. Under these conditions, the parameter θ cannot be estimated from any finite data segment unless further constraints are imposed.

The Role of Regularization in Linear System Identification

In order to simplify the presentation, we shall refer to the linear model (1) and assume that $H(q) = 1$, i.e., we consider the so-called linear output-error (OE) models. The extension to more

S

general model classes can be found in Pillonetto et al. (2011), Chen et al. (2012), Chiuso and Pillonetto (2012), and references therein.

The main purpose of regularization is to control the model complexity in a flexible manner, moving from families of rigid, finite dimensional parametric model classes $\mathcal{M}_n(\theta)$ to flexible, possibly infinite dimensional, models. To this purpose one starts with a "suitably large" model class which is constrained through the use of socalled regularization functionals. To simplify the presentation, we consider the FIR (2). The estimator $\hat{\theta}$ is found as the solution of the following optimization problem

$$\hat{\theta} = \arg \min_{\theta \in \mathbb{R}^n} J_F(\theta) + J_R(\theta; \lambda) \quad (3)$$

where $J_F(\theta)$ is the "fit" term often measured in terms of average squared prediction errors:

$$J_F(\theta) := \frac{1}{N} \sum_{t=1}^{N} \| y_t - \hat{y}_{t|t-1}(\theta) \|^2 \quad (4)$$

while $J_R(\theta; \lambda)$ is a regularization term which penalizes certain parameter vectors θ associated to "unlikely" systems. Equation (3) can be seen as a way to deal with the *bias-variance tradeoff*. The regularization term $J_R(\theta; \lambda)$ may depend upon some regularization parameters λ which need to be tuned using measured data. In its simplest instance,

$$J_R(\theta; \lambda) = \lambda J_R(\theta)$$

where λ is a scale factor that controls "how much" regularization is needed. We now discuss different forms of regularization $J_R(\theta; \lambda)$ which have been studied in the literature.

Example 8 Let us consider the FIR model in Eq. (2) and let θ be a vector containing all the unknown coefficients of the impulse response $\{g_k\}_{k=1,\dots,T}$. The linear least squares estimator

$$\hat{\theta}_{LS} := \arg \min_{\theta} \frac{1}{N} \sum_{t=1}^{N} \| y_t - \hat{y}_{t|t-1}(\theta) \|^2 \quad (5)$$

is ill-posed unless the number of data N is larger (and in fact much larger) that the number of parameters T. From the statistical point of view, the estimator (5) would result for large T in small bias and large variance. The purpose of regularization is to render the inverse problem of finding θ from the data $\{y_t\}_{t=1,\dots,N}$ well posed, thus better trading bias versus variance. The simplest form of regularization is indeed the socalled ridge regression or its weighted version (aka generalized Tikhonov regularization), where the 2-norm of the vector θ is weighted w.r.t. a positive semidefinite matrix Q,

$$\hat{\theta}_{\text{Reg}} := \arg \min_{\theta} \frac{1}{N} \sum_{t=1}^{N} \| y_t - \hat{y}_{t|t-1}(\theta) \|^2$$
$$+ \lambda \theta^\top Q \theta \quad (6)$$

which result in so-called regularization for smoothness; see section "Regularization for Smoothness." The choice of the weighting Q is highly nontrivial in the system identification context, and the performance of the regularized estimator $\hat{\theta}_{\text{Reg}}$ heavily depends on this.

Remark 2 In order to formalize these ideas for nonparametric models or, equivalently, when the parameter θ is infinite dimensional, one has to bring in functional analytic tools, such as reproducing kernel Hilbert spaces (RKHS). This is rather standard in the literature on ill-posed inverse problems and has been recently introduced also in the system identification setting (Pillonetto et al. 2011). We shall not discuss these issues here because, we believe, the formalism would render the content less accessible.

Note that this regularization approach admits a completely equivalent Bayesian formulation simply setting

$$p(y|\theta) \propto e^{-J_F(\theta)} \quad p(\theta|\lambda) \propto e^{-J_R(\theta; \lambda)} \quad (7)$$

The densities $p(y|\theta)$ and $p(\theta|\lambda)$ are, respectively, the likelihood function and the prior, which in turn may depend on the unknown regularization parameters λ, aka hyperparameters in this Bayesian formulation. This is straightforward in

the finite dimensional setting, while it requires some care when θ is infinite dimensional. With reference to Example 7, and assuming θ contains the impulse response coefficients g_k in (2), $p(\theta|\lambda)$ is a Gaussian density with zero mean and covariance Σ which may be depend upon some regularization parameters λ. From the definitions (7), it follows that

$$p(\theta|y, \lambda) \propto p(y|\theta) p(\theta|\lambda) \qquad (8)$$

from which point estimators of θ can be obtained (e.g., as posterior mean, MAP, etc.). As such, with some abuse of terminology, we shall indifferently refer to $J_R(\theta; \lambda)$ as the "regularization term" or the "prior." The unknown parameter λ is used to introduce some flexibility in the regularization term $J_R(\theta; \lambda)$ or equivalently in the prior $p(\theta|\lambda)$ and is tuned based on measured data as discussed later on.

The regularization term $J_R(\theta; \lambda)$ can be roughly classified in *regularization for smoothness*, which attempts to control complexity in a smooth fashion and *regularization for sparseness* which, on top of estimation, also aims at selecting among a finite (yet possibly very large) number of candidate model classes.

Regularization for Smoothness

Let us consider a single-input, single-output FIR model of length T (arbitrarily large) and let $\theta := [g_1 \ g_2 \ \dots g_T]^\top \in \mathbb{R}^T$ be the (finite) impulse response; define also $y \in \mathbb{R}^N$ be the vector of output observations, Φ the regressor matrix with past input samples, and e the vector with innovations (zero mean, variance $\sigma^2 I$). With this notation the convolution input-output equation (1) takes the form

$$y = \Phi\theta + e$$

Following the prescriptions of ridge regression, a regularized estimator $\hat{\theta}$ can be found setting

$$J_R(\theta; \lambda) = \theta^\top K^{-1}(\lambda)\theta \qquad (9)$$

where the matrix $K(\lambda)$, aka kernel, is tailored to capture specific properties of impulse responses (exponential decay, BIBO stability, smoothness, etc.). Early references include Doan et al. (1984) and Kitagawa and Gersh (1984), while more recent work can be found in Pillonetto and De Nicolao (2010), Pillonetto et al. (2011) and Chen et al. (2012) where several choices of kernels are discussed.

Example 9 The simplest example of kernel is the so-called "exponentially decaying" kernel

$$K(\lambda) := \gamma D(\rho) \quad D(\rho) := \text{diag}\{\rho, \dots, \rho^T\} \qquad (10)$$

where $\lambda := (\gamma, \rho)$ with $0 < \rho < 1$ and $\gamma \geq 0$.

For fixed λ, the estimator $\hat{\theta}(\lambda)$ is the solution of a quadratic problem and can be written in closed form (aka ridge regression):

$$\hat{\theta}(\lambda) = K(\lambda)\Phi^\top \left(\Phi K(\lambda)\Phi^\top + \sigma^2 I\right)^{-1} y \qquad (11)$$

Two common strategies adopted to estimate the parameters λ are cross validation (Ljung 1999) and marginal likelihood maximization. This latter approach is based on the Bayesian interpretation given in Eqs. (7) from which one can compute the so-called "empirical Bayes" estimator $\hat{\theta}_{\text{EB}} := \hat{\theta}(\hat{\lambda}_{\text{ML}})$ of θ plugging in (11) the estimator of λ which maximizes the marginal likelihood:

$$\hat{\lambda}_{\text{ML}} := \arg \max_\lambda p(\lambda|y)$$
$$= \arg \max_\lambda \int p(\lambda, \theta|y) \, d\theta \qquad (12)$$

The main strength of the marginal likelihood is that, by integrating the joint posterior over the unknown hyperparameters θ, it automatically accounts for the residual uncertainty in θ for fixed λ. When both J_F and J_R are quadratic costs, which corresponds to assuming that e and θ are independent and Gaussian, the marginal likelihood in (12) can be computed in closed form so that

$$\hat{\lambda}_{\mathrm{ML}} := \arg \min_{\lambda} \ \log(\det(\Sigma(\lambda)))$$

$$+ \ y^{\top} \Sigma^{-1}(\lambda) y$$

$$\Sigma(\lambda) := \Phi K(\lambda) \Phi^{\top} + \sigma^2 I \qquad (13)$$

It is here interesting to observe that $\hat{\lambda}_{\mathrm{ML}}$ which solves (12) under certain conditions leads to $K(\hat{\lambda}_{\mathrm{ML}}) = 0$ (see Example 10), so that the estimator of θ in (11) satisfies $\hat{\theta}(\hat{\lambda}_{\mathrm{ML}}) = 0$. This simple observation is the basis of so-called *sparse Bayesian learning* (SBL); we shall return to this issue in the next section when discussing regularization for sparsity and selection.

Unfortunately the optimization problem (12) (or (13)) is not convex and thus subjected to the issue of local minima. However, both experimental evidence and some theoretical results support the use of marginal likelihood maximization for estimating regularization parameters; see, e.g., Rasmussen and Williams (2006) and Aravkin et al. (2014).

Regularization for Sparsity: Variable Selection and Order Estimation

The main purpose of regularization for sparseness is to provide estimators $\hat{\theta}$ in which subsets or functions of the estimated parameters are equal to zero.

Consider the multi-input, multi-output OE model

$$y_{t,j} = \sum_{i=1}^{m} \sum_{k=1}^{T} g_{k,ij} u_{t-k,i} + e_{t,i} \quad j = 1, \dots, p \tag{14}$$

where $y_{t,j}$ denotes the jth component of $y_t \in \mathbb{R}^p$; let also $\theta \in \mathbb{R}^{T(m+p)}$ be the vector containing all the impulse response coefficients $g_{k,ij}$, $j = 1, \dots, p$, $i = 1, \dots, m$, and $k = 1, \dots, T$. With reference to Eq. (14), simple examples of sparsity one may be interested in are:

(i) Single elements of the parameter vector θ, which corresponds to eliminating specific lags of some variables from the model (14).

(ii) Groups of parameters such as the impulse response from ith input to the jth output

$g_{k,ij}$, $k = 1, \dots, T$, thereby eliminating the ith input from the model for the jth output.

(iii) The singular values of the Hankel matrix $\mathcal{H}(\theta)$ formed with the impulse response coefficients g_k; in fact the rank of the Hankel matrix equals the order (i.e., the McMillan degree) of the system. (Strictly speaking any full rank FIR model of length T has McMillan degree $T \times p$. Yet, we consider $\{g_k\}_{k=1,\dots,T}$ to be the truncation of some "true" impulse response $\{g_k\}_{k=1,\dots,\infty}$, and, as such, the finite Hankel matrix built with the coefficients g_k will have rank equal to the McMillan degree of $G(q) = \sum_{k=1}^{\infty} g_k z^{-k}$.)

To this purpose one would like to penalize the number of nonzero terms, let them be entries of θ, groups, singular values, etc. This is measured by the ℓ_0 quasinorm or its variations: group ℓ_0 and ℓ_0 quasinorm of the Hankel singular values, i.e., the rank of the Hankel matrix. Unfortunately if J_R is a function of the ℓ_0 quasinorm, the resulting optimization problem is computationally intractable; as such one usually resorts to relaxations. Three common ones are described below.

One possibility is to resort to greedy algorithms such as orthogonal matching pursuit; generically it is not possible to guarantee convergence to a global minimum point.

A very popular alternative is to replace the ℓ_0 quasinorm by its *convex envelope*, i.e., the ℓ_1 norm, leading to algorithms known in statistics as LASSO (Tibshirani 1996) or its group version Group LASSO (Yuan and Lin 2006):

$$J_R(\theta; \lambda) = \lambda \|\theta\|_1 \tag{15}$$

Similarly the convex relaxation of the rank (i.e., the ℓ_0 quasinorm of the singular values) is the so-called nuclear norm (aka Ky Fan n-norm or trace norm), which is the sum of the singular values $\|A\|_* := \mathrm{trace}\{\sqrt{A^{\top} A}\}$ where $\sqrt{\cdot}$ denotes the matrix square root which is well defined for positive semidefinite matrices. In order to control the order (McMillan degree) of a linear system, which is equal to the rank of the Hankel matrix $\mathcal{H}(\theta)$ built with the impulse response described

by the parameter θ, it is then possible to use the regularization term

$$J_R(\theta; \lambda) = \lambda \|\mathcal{H}(\theta)\|_* \qquad (16)$$

thus leading to convex optimization problems (Fazel et al. 2001). Both (16) and (15) induce sparse or nearly sparse solutions (in terms of elements or groups of θ (15) or in terms of Hankel singular values (16)), making them attractive for selection. It is interesting to observe that both ℓ_1 and group ℓ_1 are special cases of the nuclear norm if one considers matrices with fixed eigenspaces. Yet, as well documented in the statistics literature, both (16) and (15) do not provide a satisfactory trade-off between sparsity and shrinking, which is controlled by the regularization parameter λ. As λ varies one obtains the so-called *regularization path*. Increasing λ the solution gets sparser but, unfortunately, it suffers from shrinking of nonzero parameters. To overcome these problems, several variations of LASSO have been developed and studied, such as adaptive LASSO (Zou 2006), SCAD (Fan and Li 2001), and so on. We shall now discuss a Bayesian alternative which, to some extent, provides a better trade-off between sparsity and shrinking than the ℓ_1 norm.

This Bayesian procedure goes under the name of sparse Bayesian learning and can be seen as an extension of the Bayesian procedure for regularization described in the previous section. In order to illustrate the method, we consider its simplest instance. Consider an MIMO system as in (14) with $p = 1$ and $m = 2$, i.e.,

$$\begin{aligned} y_t &= \sum_{k=1}^{T} g_{k,1} u_{t-k,1} + \sum_{k=1}^{T} g_{k,2} u_{t-k,2} + e_t \\ &= \phi_{t,1}^\top g_1 + \phi_{t,2}^\top g_2 + e_t \end{aligned} \qquad (17)$$

where $g_i := [g_{1,i}, \ldots, g_{t,i}]$. Let $\theta := [g_1^\top \ g_2^\top]^\top$ and assume that the g_i's are independent Gaussian random vectors with zero mean and covariances $\lambda_i K$. Letting $\Phi_i := [\phi_{1,i}, \ldots, \phi_{N,i}]^\top$ and following the formulation in (7) and (8), it follows that the marginal likelihood estimator of λ takes the form

$$\hat{\lambda}_{\mathrm{ML}} := \arg \min_{\lambda_i \geq 0} \log(\det(\Sigma(\lambda))) + y^\top \Sigma^{-1}(\lambda) y$$

$$\Sigma(\lambda) := \lambda_1 \Phi_1 K \Phi_1^\top + \lambda_2 \Phi_2 K \Phi_2^\top + \sigma^2 I \qquad (18)$$

After $\hat{\lambda}_{\mathrm{ML}}$ has been found, the estimator of θ is found in closed form as per Eq. (11). It can be shown that under certain conditions on the observation vector y, the estimated hyperparameters $\hat{\lambda}_{\mathrm{ML},i}$ lie at the boundary, i.e., are exactly equal to zero. If $\hat{\lambda}_{\mathrm{ML},i} = 0$, then, from Eq. (11), also $\hat{g}_i = 0$; this reveals that in (17) the ith input does not enter into the model; see also Example 10 for a simple illustration.

These Bayesian methods for sparsity have been studied in a general regression framework in Wipf et al. (2011) under the name of "type-II" maximum likelihood. Further results can be found in Aravkin et al. (2014) which suggest that these Bayesian methods provide a better trade-off between sparsity and shrinking (i.e., are able to provide sparse solution without inducing excessive shrinkage on the nonzero parameters).

Remark 3 A more detailed analysis, see, for instance, Aravkin et al. (2014), shows that LASSO/GLASSO (i.e., ℓ_1 penalties) and SBL using the "empirical Bayes" approach can be derived under a common Bayesian framework starting from the joint posterior $p(\lambda, \theta|y)$. While SBL is derived from the maximization λ of the marginal posterior, LASSO/GLASSO corresponds to maximizing the joint posterior after a suitable change of variables. For reasons of space, we refer the interested reader to the literature for details.

Recent work on the use of sparseness for variable selection and model order estimation can be found in Wang et al. (2007), Chiuso and Pillonetto (2012); and references therein.

Example 10 In order to illustrate how sparse Bayesian learning leads to sparse solutions, we consider a very simplified scenario in which the measurements equation is

$$y_t = \theta u_{t-1} + e_t$$

where e_t is zero-mean, unit variance Gaussian and white and u_t is a deterministic signal. The purpose is to estimate the coefficient θ, which could be possibly equal to zero. Thus, the estimator should reveal whether u_{t-1} influences y_t or not.

Following the SBL framework, we model θ as a Gaussian random variable, with zero mean and variance λ, independent of e_t. Therefore, y_t is also Gaussian, zero mean, and variance $u_{t-1}^2\lambda+1$. Therefore, assuming N data points are available, the likelihood function for λ is given by

$$L(\lambda) = \prod_{i=1}^{N} \frac{1}{\sqrt{2\pi(u_{t-1}^2\lambda + 1)}} e^{-\frac{1}{2}\sum_{i=1}^{N}\frac{y_t^2}{u_{t-1}^2\lambda + 1}}$$

Defining now

$$\hat{\lambda}_{\mathrm{ML}} := \arg\min_{\lambda \geq 0} -2\log L(\lambda)$$

one obtains that

$$\hat{\lambda}_{\mathrm{ML}} = \max(0, \lambda_*)$$

where λ_* is the solution of

$$\sum_{t=1}^{N} \frac{u_{t-1}^4\lambda + u_{t-1}^2\left(1 - y_t^2\right)}{u_{t-1}^2\lambda + 1} = 0$$

which unfortunately doesn't have a closed form solution. If however we assume that the input u_t is constant (without loss of generality say that $u_t = 1$), we obtain that

$$\lambda_* = \frac{1}{N}\sum_{t=1}^{N} y_t^2 - 1$$

thus

$$\hat{\lambda}_{\mathrm{ML}} = \max\left(0, \frac{1}{N}\sum_{t=1}^{N} y_t^2 - 1\right)$$

Clearly this is a threshold estimator which sets to zero $\hat{\lambda}_{\mathrm{ML}}$ when the sample variance of y_t

is smaller than the variance of e_t, which was assumed to be equal to 1. Thus, the empirical Bayes estimator of θ, as per Eq. (11), is given by

$$\hat{\theta} = \frac{\hat{\lambda}_{\mathrm{ML}}}{\sum_{i=1}^{N} u_{t-1}^2\hat{\lambda}_{\mathrm{ML}} + 1} \sum_{i=1}^{N} y_t u_{t-1}$$

which is clearly equal to zero when $\hat{\lambda}_{\mathrm{ML}} = 0$.

Extensions: Regularization for Hybrid Systems Identification and Model Segmentation

An interesting extension of linear systems is a class of so-called hybrid models described by a relation of the form

$$
\begin{aligned}
y_t &= \hat{y}_{\theta_k}(t|t-1) + e_t \\
\hat{y}_{\theta_k}(t|t-1) &= L_{\theta_k}(y_t^-, u_t^-) \\
\theta_k &\in \mathbb{R}^{n_k} \quad k = 1, \ldots, K
\end{aligned}
\tag{19}
$$

where the predictor $\hat{y}_{\theta_k}(t|t-1)$, which is a linear function $L_{\theta_k}(y_t^-, u_t^-)$ of the "past" histories $y_t^- := \{y_{t-1}, y_{t-2}, \ldots\}$ and $u_t^- := \{u_{t-1}, u_{t-2}, \ldots\}$, is parametrized by a parameter vector $\theta_k \in \mathbb{R}^{n_k}$; there are K different parameter vectors θ_k, $k = 1, \ldots, K$, whose evolution over time is determined by a so-called *switching mechanism*. The name *hybrid* hints at the fact that the model is described continuous-valued (y, u, and e) and discrete-valued (k) variables.

A well-studied subclass of (19) is composed by the so-called switching ARX models, where the predictor takes the special form

$$\hat{y}_{\theta_k}(t|t-1) = \phi_t^\top \theta_k \quad \theta_k \in \mathbb{R}^{n_k} \tag{20}$$

The regressor ϕ_t is a finite vector containing inputs u_s and outputs y_s in a finite past window $s \in [t-1, t-T]$, plus possibly a constant component to model changing "means." The value of $k \in [1, K]$ is determined by the switching mechanism $p(\phi_t, t) : \mathbb{R}^{n_k} \times \mathbb{R} \to \{1, \ldots, K\}$.

Two extreme but interesting cases are (i) $p(\phi_t, t) = p_t$, where $p(\cdot)$ is an exogenous and not measurable signal, and (ii) $p(\phi_t, t) = p(\phi_t)$,

where $p(\cdot)$ is an endogenous unknown measurable function of the regression vector ϕ_t. In any case, from the identification point of view, k at time t *is not* assumed to be known and, as such, the identification algorithm has to operate without knowledge of this switching mechanism.

Identification of systems in the form (20) requires to estimate (a) the number of models K and the position of the switches between different models, (b) the "dimension" of each model n_k, (c) the value of the parameters θ_k, and, possibly, (d) the function $p(\phi_t, t)$ which determines the switching mechanism.

Steps (b) and (c) are essentially as in section "System Identification" (see also the introductory paper ▸ System Identification: An Overview); however, this is complicated by steps (a) and (d), which in particular require that one is able to estimate, from data alone, which system is "active" at each time t.

Step (a), which is also related to the problem of *model segmentation*, has been tackled in the literature; see e.g., Ozay et al. (2012), Ohlsson and Ljung (2013), and references therein, by applying suitable penalties on the number of different models K and/or on the number of switches. Note that $p(\phi_t, t) \neq p(\phi_s, s)$ if and only if $\theta_t \neq \theta_s$. Based on this simple observation, one can construct a regularization which counts either the number of switches, i.e.,

$$J_R(\theta; \gamma) := \gamma \sum_{t=2}^{N} \|\|\theta_t - \theta_{t-1}\|\|_0, \quad (21)$$

or attempts to approximate the total number of different models computing

$$J_R(\theta; \gamma) := \gamma \sum_{t,s=1}^{N} w(s,t)\|\|\theta_t - \theta_s\|\|_0 \quad (22)$$

for a suitable weighting $w(t,s)$; see Ohlsson and Ljung (2013).

As discussed above, these quasinorms lead, in general, to unfeasible optimization problems (NP-hard). An exception is the case where one considers bounded noise, i.e., solves a problem of the form

$$\min_{\theta_t} \sum_{t=2}^{N} \|\theta_t - \theta_{t-1}\|_0 \quad s.t. \quad \|y_t - \phi_t^\top \theta_t\|_\infty < \epsilon \quad (23)$$

which is shown to be a convex problem; see Ozay et al. (2012). In general relaxations are used, typically using the ℓ_1/group-ℓ_1 penalties, thus relaxing (21) and (22) to

$$\begin{aligned} J_R(\theta; \lambda) &:= \lambda \sum_{t=2}^{N} \|\theta_t - \theta_{t-1}\|_1 \\ J_R(\theta; \lambda) &:= \lambda \sum_{t,s=1}^{N} w(s,t)\|\theta_t - \theta_s\|_1 \end{aligned} \quad (24)$$

This yields to the convex optimization problems:

$$\min_{\theta_t} \sum_t \left(y_t - \phi_t^\top \theta_t\right)^2 + \lambda \sum_{t=2}^{N} \|\theta_t - \theta_{t-1}\|_1 \quad (25)$$

or

$$\min_{\theta_t} \sum_t \left(y_t - \phi_t^\top \theta_t\right)^2 + \lambda \sum_{t,s=1}^{N} w(s,t)\|\theta_t - \theta_s\|_1 \quad (26)$$

Summary and Future Directions

We have presented a bird's eye overview of regularization methods in system identification. By necessity this overview was certainly incomplete and we encourage the reader to browse through the recent literature for new developments on this exciting topic; we hope the references we have provided are a good starting point. While regularization is quite an old topic, we believe it is fair to say that the nontrivial interaction between regularization and system theoretic concepts provides a wealth of interesting and challenging problems. Just to mention a few open questions: (i) how and why smoothness priors relate to system order (McMillan degree), (ii) how can one design kernels which, at the same time, are descriptive for dynamical systems and lead to computationally attractive problems suited for online identification, (iii) how should kernels for multi-output systems be designed, and (iv) which are the statistical properties of Bayesian

procedures such as SBL and its extensions in the context of system identification. Last but not least, while some results are available, nonlinear system identification still offers significant challenges.

Recommended Reading

The use of regularization methods for system identification can be traced back to the 1980s, see Doan et al. (1984) and Kitagawa and Gersh (1984); yet it is fair to say that the most significant developments are rather recent and therefore the literature is not established yet. The reader may consult Fazel et al. (2001), Pillonetto et al. (2011), Chen et al. (2012), Chiuso and Pillonetto (2012) and references therein. Clearly all this work has largely benefitted from cross fertilization with neighboring areas and, as such, very relevant work can be found in the fields of machine learning (Bach et al. 2004; Mackay 1994; Tipping 2001; Rasmussen and Williams 2006), statistics (Hocking 1976; Tibshirani 1996; Fan and Li 2001; Wang et al. 2007; Yuan and Lin 2006; Zou 2006), signal processing (Donoho 2006; Wipf et al. 2011) and econometrics (Banbura et al. 2010).

System Identification: An Overview

Lennart Ljung
Division of Automatic Control, Department of Electrical Engineering, Linköping University, Linköping, Sweden

Abstract

This entry gives an overview of system identification. It outlines the basic concepts in the area and also serves as an umbrella contribution for the related nine articles on system identifications in this encyclopedia. The basis is the classical statistical approach of parametric methods using maximum likelihood and prediction error methods. The paper also describes the properties of the estimated models for large data sets.

Keywords

Asymptotic model properties; Dynamical systems; Estimation; Mathematica models; Maximum likelihood; Parameter estimates; Prediction error method; Regularization

An Introductory Example

System identification is the theory and art of estimating models of dynamical systems, based on observed inputs and outputs. Consider as a concrete example the Swedish aircraft fighter Gripen; see Fig. 1. From one of the earlier test flights, some data were recorded as depicted in Fig. 2.

To design the simulation software and the autopilot, the aircraft manufacturer, the SAAB company, needed a mathematical model for the dynamics of the system. It is a question to describe how, in this case, the pitch rate is affected by the three inputs. A fair amount of knowledge exists about aircraft dynamics, and in industrial practice, "gray-box" models based on Newton's laws of motion and unknown parameters like aerodynamical derivatives are employed to estimate the flight dynamics. Here, for the purpose of illustrating basic principles, let us just try a simple "black-box" difference equation relation. Denote the output, the pitch rate, at sample number t by $y(t)$, and three control inputs at the same time by $u_k(t), k = 1, 2, 3$. Then assume that we can write

$$
\begin{aligned}
y(t) = &- a_1 y(t-1) - a_2 y(t-2) - a_3 y(t-3) \\
&+ b_{1,1} u_1(t-1) + b_{1,2} u_1(t-2) \\
&+ b_{2,1} u_2(t-1) + b_{2,2} u_2(t-2) \\
&+ b_{3,1} u_3(t-1) + b_{3,2} u_3(t-2)
\end{aligned} \tag{1}
$$

In this simple relationship, we can adjust the parameters to fit the observed data as well as possible by a common least squares fit. We use only the 90 first data points of the observed data. That gives certain numerical values of the 9 parameters above:

$$
\begin{aligned}
&a_1 = -1.15, \, a_2 = 0.50, \, a_3 = -0.35, \\
&b_{1,1} = -0.54 \, b_{1,2} = 0.4, \, b_{2,1} = 0.15, \\
&b_{2,2} = 0.16, \, b_{3,1} = 0.16, \, b_{3,2} = 0.07
\end{aligned} \tag{2}
$$

We may note that this model is unstable – it has a pole at 1.0026, but that is in order, because the pitch channel of the real aircraft is unstable at the velocity and altitude in question.

How can we test if this model is reasonable? Since we used only half of the observed data for the estimation, we can test the model on the whole data record. Since the model is unstable it is natural to test it by letting it predict future outputs, say five samples ahead, and compare with the measured outputs. That is done in

leading edge flap. (**d**) Control input 3: canard angle

Fig. 3. We see that the simple model (2) provides
quite reasonable predictions over data it has
not seen before. This could conceivably be
improved if more elaborate model structures

than (1) were tried out. Also, in practice more
advanced techniques would be required to
validate that the estimated model is sufficiently
reliable.

System Identification: An Overview, Fig. 3 The measured output (*solid line*) compared to the 5-step-ahead prediction one (*dashed line*)

This simple introductory example points to the basic flow of system identification and it also points to the pertinent issues, which will be listed in the section "The State-of-the-Art Identification Setup."

Models and System Identification

The Omnipresent Model

It is clear to everyone in science and engineering that *mathematical models* are playing increasingly important roles. Today, model-based design and optimization is the dominant engineering paradigm to systematic design and maintenance of engineering systems. It has proven very successful and is widely used in basically all engineering disciplines. Concerning control applications, the aerospace industry is the earliest example on a grand-scale of this paradigm. This industry was very quick to adopt the theory for model-based optimal control that emerged in the 1960s and is spending great efforts and resources on developing models. In the process industry, model predictive control (MPC) has during the last 25 years become the dominant method to optimize production on an intermediate level. MPC uses dynamical models to predict future process behavior and to optimize the manipulated variables subject to process constraints.

Increasing demands on performance, efficiency, safety, and environmental aspects are pushing engineering systems to become increasingly complex. Advances in (wireless) communications systems and microelectronics are key enablers for this rapid development, allowing systems to be efficiently interconnected in networks, reducing costs and size, and paving the way for new sensors and actuators.

Model-based techniques are also gaining importance outside engineering applications. Let us just mention systems biology and health care. In the latter case it is expected that personalized health systems will become more and more important in the future.

Common to the examples given above are the requirements of permeating sensing, actuation, communication, and computation abilities of the engineering systems, in many cases in distributed architectures. It is also clear that these systems should be able to operate in a reliable way in an uncertain and temporally and spatially changing environment. In many applications, cognitive abilities and abilities to adapt will be important. With systems being decentralized and typically containing many actuators, sensors, states, and nonlinearities, but with limited access to sensor information, model building that delivers models of sufficient fidelity becomes very challenging.

System Identification: Data-Driven Modeling

Construction of models requires access to observed data. It could be that the model is developed entirely from information in signals from the system ("black-box models") or it could be that physical/engineering insights are combined with such information ("gray-box models"). In any case, verification (validation) of a model must be done in the light of measured data. Theories and methodologies for such model construction have been developed in many different research communities (to some extent independently). *System identification* is the term used in the control community for

the area of constructing mathematical models of dynamical systems from measured input-output signals. Other communities use other terms for often very similar techniques. The term *machine learning* has become very common in recent years, e.g., Rasmussen and Williams (2006).

System identification has a history of more than 50 years, since the term was coined by Lotfi Zadeh (1956). It is a mature research field with numerous publications, textbooks, conference series, and software packages. It is often used as an example in the control field of an area with good interaction between theory and industrial practice. The backbone of the theory relies upon statistical grounds, with maximum likelihood methods and asymptotic analysis (in the number of observed data). The goal of the system identification field is to find a model of the plant in question as well as of its disturbances and also to find a characterization of the uncertainty bounds of the description.

The State-of-the-Art Identification Setup

To approach a system identification problem, like in section "An Introductory Example," a number of questions need to be answered, such as
- What model type, e.g., (1) should be used?
- How should the parameters in the model be adjusted?
- What inputs should be applied to obtain a good model?
- How do we assess the quality of the model?
- How do we gain confidence in an estimated model?

There is a very extensive literature on the subject, with many textbooks, like Ljung (1999), Söderström and Stoica (1989), and Pintelon and Schoukens (2012).

System identification is characterized by five basic concepts:
- $\mathcal{X}$: The experimental conditions under which the data is generated
- $\mathcal{D}$: The data
System Identification: An Overview, Fig. 4 The identification work loop

- $\mathcal{M}$: The model structure and its parameters θ
- $\mathcal{I}$: The identification method by which a parameter value $\hat{\theta}$ in the model structure $\mathcal{M}(\theta)$ is determined based on the data $\mathcal{D}$
- $\mathcal{V}$: The validation process that scrutinizes the identified model

See Fig. 4. It is typically an iterative process to navigate to a model that passes through the validation test ("is not falsified"), involving revisions of the necessary choices. For several of the steps in this loop, helpful support tools have been developed. It is however not quite possible or desirable to fully automate the choices, since subjective perspectives related to the intended use of the model are very important.

$\mathcal{M}$: Model Structures

A model structure $\mathcal{M}$ is a parameterized collection of models that describe the relations between the inputs u and outputs y of the system. The parameters are denoted by θ so $\mathcal{M}(\theta)$ is a particular model. The model set then is

$$\mathcal{M} = \{\mathcal{M}(\theta) | \theta \in D_{\mathcal{M}}\} \qquad (3)$$

Many ways exist to collect mathematical expressions that encompass a model; see, e.g., ▶ Modeling of Dynamic Systems from First Principles, ▶ Nonlinear System Identification: An Overview of Common Approaches, and

▶ Nonlinear System Identification Using Particle Filters. The models may be both linear and nonlinear as well as time invariant and time varying, and it is useful to have as a common ground that a model gives a rule to predict (one-step-ahead) the output at time t, i.e., $y(t)$ (a p-dimensional column vector), based on observations of previous input-output data up to time $t - 1$ (denoted by Z^{t-1}).

$$\hat{y}(t|\theta) = g(t, \theta, Z^{t-1}) \qquad (4)$$

This covers a broad variety of model descriptions, sometimes in a somewhat abstract way. The descriptions become much more explicit when we specialize to linear models.

A note on "inputs" It is important to include all measurable disturbances that affect y among the inputs u to the system, even if they cannot be manipulated as control inputs. In some cases the system may entirely lack measurable inputs, so the model (4) then just describes how future outputs can be predicted from past ones. Such models are called *time series* and correspond to systems that are driven by unobservable disturbances. Most of the techniques described in this entry apply also to such models.

A note on disturbances A complete model involves both a description of the input-output relations and a description of how various noise sources affect the measurements. The noise description is essential to understand both the quality of the model predictions and the model uncertainty. Proper control design also requires a picture of the disturbances in the system.

Linear Models

For linear time invariant systems, a general model structure is given by the transfer function G from input u to output y and the transfer function H from a white noise source e to output additive disturbances (for notational convenience, we specialize to single-input-single-output systems, but all expressions are valid in the multivariable case with simple notational changes):

$$y(t) = G(q, \theta)u(t) + H(q, \theta)e(t) \qquad (5a)$$

$$Ee^2(t) = \sigma^2; \quad Ee(t)e^T(k) = 0 \text{ if } k \neq t \qquad (5b)$$

(E denotes mathematical expectation.) This model is in discrete time and q denotes the shift operator $qy(t) = y(t + 1)$. We assume for simplicity that the sampling interval is a one-time unit. The expansion of $G(q, \theta)$ in the inverse (backwards) shift operator gives the *impulse response* of the system:

$$G(q, \theta)u(t) = \sum_{k=1}^{\infty} g_k(\theta)q^{-k}u(t)$$

$$= \sum_{k=1}^{\infty} g_k(\theta)u(t - k) \qquad (6)$$

The discrete time Fourier transform (or the z-transform of the impulse response, evaluated in $z = e^{i\omega}$) gives the *frequency response* of the system:

$$G(e^{i\omega}, \theta) = \sum_{k=1}^{\infty} g_k(\theta)e^{-ik\omega} \qquad (7)$$

The function G describes how an input sinusoid shifts phase and amplitude when it passes through the system.

The additive noise term $v = He$ is quite versatile, and with a suitable choice of H, it can describe a disturbance with arbitrary spectrum. To link with the predictor as a unifying model concept, it is useful to compute the predictor for (5a) (the conditional mean of $y(t)$ given past data), which is

$$\hat{y}(t|\theta) = G(q, \theta)u(t) + [1 - H^{-1}(q, \theta)]$$
$$[y(t) - G(q, \theta)u(t)] \qquad (8)$$

Note that the expansion of H^{-1} starts with "1," so the first term starts with $h_1 q^{-1}$ so there is a delay in y. It is easy to interpret the first term as a simulation using the input u, adjusted with a prediction of the additive disturbance $v(t)$ at

time t, based on past values of v. The predictor is thus an easy reformulation of the basic transfer functions G and H. The question now is how to parameterize these.

Black-Box Models

A *black-box* model uses no physical insight or interpretation, but is just a general and flexible parameterization. It is natural to let G and H be rational in the shift operator:

$$G(q, \theta) = \frac{B(q)}{F(q)}; \quad H(q, \theta) = \frac{C(q)}{D(q)} \quad \text{(9a)}$$

$$B(q) = b_1 q^{-1} + b_2 q^{-2} + \ldots b_{nb} q^{-nb} \quad \text{(9b)}$$

$$F(q) = 1 + f_1 q^{-1} + \ldots + f_{nf} q^{-nf} \quad \text{(9c)}$$

$$\theta = [b_1, b_2, \ldots, f_{nf}] \quad \text{(9d)}$$

C and D are like F *monic*, i.e., start with a "1."

A very common case is that $F = D = A$ and $C = 1$ which gives the *ARX model* (autoregressive with exogenous input):

$$y(t) = A^{-1}(q)B(q)u(t) + A^{-1}(q)e(t) \text{ or} \quad \text{(10a)}$$

$$A(q)y(t) = B(q)u(t) + e(t) \text{ or} \quad \text{(10b)}$$

$$y(t) + a_1 y(t-1) + \ldots + a_{na} y(t - na) \quad \text{(10c)}$$

$$= b_1 u(t-1) + \ldots + b_{nb} u(t - nb) \quad \text{(10d)}$$

This is the model structure we used in (1) in the introductory example, but for several inputs.

Other common black-box structures of this kind are FIR (finite impulse response model, $F = C = D = 1$), ARMAX (autoregressive moving average with exogenous input, $F = D = A$), and BJ (Box-Jenkins, all four polynomials are different.)

Gray-Box Models

If some physical facts are known about the system, it is possible to build that into a *gray-box model*. It could, for example, be that for the airplane in the introduction, the motion equations are known from Newton's laws, but certain parameters are unknown, like the aerodynamical derivatives. Then it is natural to build a continuous-time state-space model from physical equations:

$$\dot{x}(t) = A(\theta)x(t) + B(\theta)u(t)$$
$$y(t) = C(\theta)x(t) + D(\theta)u(t) + v(t) \quad \text{(11)}$$

Here θ are simply some entries of the matrices A, B, C, D, corresponding to unknown physical parameters, while the other matrix entries signify known physical behavior. This model can be sampled with well-known sampling formulas (obeying the input inter-sample properties, zero-order hold, or first-order hold) to give

$$x(t + 1) = \mathcal{F}(\theta)x(t) + \mathcal{G}(\theta)u(t)$$
$$y(t) = C(\theta)x(t) + D(\theta)u(t) + w(t) \quad \text{(12)}$$

The model (12) has the transfer function from u to y

$$G(q, \theta) = C(\theta)[qI - \mathcal{F}(\theta)]^{-1}\mathcal{G}(\theta) + D(\theta) \quad \text{(13)}$$

so we have achieved a particular parameterization of the general linear model (5a).

Continuous-Time Models

The general model description (4) describes how the predictions evolve in discrete time. But in many cases, we are interested in continuous-time (CT) models, like models for physical interpretation and simulation (e.g., electrical circuit simulators like ADS, Spice, Spectre, and Microwave Office use continuous-time models). But CT model estimation is contained in the described framework, as the linear state-space model (11) illustrates. More comments on direct estimation of CT models are given in section "Estimating Continuous Time Models."

Nonlinear Models

A nonlinear model is a relation (4), where the function g is nonlinear in the input-output data Z. There is a rich variation in how to specify the

function g more explicitly. A quite general way is the nonlinear state-space equation, which is a counterpart to (12):

$$x(t + 1) = f(x(t), v(t), \theta)$$
$$y(t) = h(x(t), e(t), \theta)$$
(14)

where v and e are white noises. This is further discussed in ▸ Nonlinear System Identification: An Overview of Common Approaches, where x is described as a Markov process with v defining the transitions, and in ▸ Nonlinear System Identification: An Overview of Common Approaches, where (14) ($v \equiv 0$) is related to a continuous-time gray-box model. The latter article also discusses several other nonlinear model structures that can be seen as extensions and modifications of linear models: nonlinear mappings of past input-output data corresponding to (10), mixing static nonlinearities with linear dynamical models, etc.

$\mathcal{I}$: Identification Methods: Criteria

The goal of identification is to match the model to the data. Here the basic techniques for such matching will be discussed.

Time Domain Data

Suppose now we have collected a data record in the time domain

$$Z^N = \{u(1), y(1), \ldots, u(N), y(N)\}$$
(15)

Since the model is in essence a predictor, it is quite natural to evaluate it by how well it predicts the measured output. So, form the prediction errors for (4):

$$\varepsilon(t, \theta) = y(t) - \hat{y}(t|\theta)$$
(16)

The "size" of this error can be measured by some scalar norm:

$$\ell(\varepsilon(t, \theta))$$
(17)

and the performance of the predictor over the whole data record Z^N becomes

$$V_N(\theta) = \sum_{t=1}^{N} \ell(\varepsilon(t, \theta))$$
(18)

A natural parameter estimate is then

$$\hat{\theta}_N = \arg\min_{\theta \in D_{\mathcal{M}}} V_N(\theta)$$
(19)

This is the *prediction error method (PEM)* and is applicable to general model structures. See, e.g., Ljung (1999) or (2002) for more details. See also ▸ Nonlinear System Identification: An Overview of Common Approaches.

The PEM approach can be embedded in a statistical setting to guarantee optimal statistical properties. The ML methodology below offers a systematic framework to do so:

A Maximum Likelihood View

If the system innovations e have a probability density function (pdf) $f(x)$, then the criterion function (18) with $\ell(x) = -\log f(x)$ will be the logarithm of the *likelihood function*. See Lemma 5.1 in Ljung (1999). More specifically, assume that the system has p outputs and that the innovations are Gaussian with zero mean and covariance matrix Λ, so that

$$y(t) = \hat{y}(t|\theta) + e(t), \quad e(t) \in N(0, \Lambda) \quad (20)$$

for the θ that generated the data. Then it follows that the negative logarithm of the likelihood function for estimating θ from y is

$$L_N(\theta) = \frac{1}{2}[V_N(\theta) + N \log \det \Lambda + Np \log 2\pi]$$
(21)

where $V_N(\theta)$ is defined by (18), with

$$\ell(\varepsilon(t, \theta)) = \varepsilon^T(t, \theta)\Lambda^{-1}\varepsilon(t, \theta)$$
(22)

So the maximum likelihood model estimate (MLE) for known Λ is obtained by minimizing $V_N(\theta)$. If Λ is not known, it can be included

S

among the parameters and estimated, (Ljung 1999, page 218), which results in a criterion

$$D_N(\theta) = \det \sum_{t=1}^{N} \varepsilon(t, \theta)\varepsilon^T(t, \theta) \qquad (23)$$

to be minimized.

The EM Algorithm

The EM algorithm (Dempster et al. 1977) is closely related to the ML technique. It is a method that is especially useful when the ML criterion is difficult to evaluate from the observed data but would be easier to find if certain unobserved *latent* variables were known. The algorithm alternates between an expectation step estimating the log likelihood and a maximization step bringing the parameter estimate closer in each step to the MLE. Its application to the nonlinear state-space model (14) is described in ▶ Nonlinear System Identification: An Overview of Common Approaches.

Regularization

Solving for the estimate in (19) is a so-called *inverse problem*, which means that the solution may be ill conditioned. To deal with that in (18), we could add a quadratic norm:

$$W_N(\theta) = V_N(\theta) + \lambda(\theta - \theta^\dagger)^T R(\theta - \theta^\dagger) \quad (24)$$

(λ is a scaling, R is a positive semidefinite (psd) matrix, and $\theta^\dagger$ is a nominal value of the parameters). The estimate is then found by minimizing $W_N(\theta)$. The criterion (24) makes sense in a classical estimation framework as an ad hoc modification of the MLE to deal with possible ill-conditioned minimization problems. The added quadratic term then serves as proper *(Tikhonov) regularization* of an ill-conditioned inverse problem; see, for example, Tikhonov and Arsenin (1977). This criterion is a clear-cut balance between model fit and a penalty on the model parameter size. The amount of penalty is governed by λ and R.

Other useful regularization penalties could be to add an ℓ_1 norm of the parameter. Such techniques are further discussed in ▶ System Identification Techniques: Convexification, Regularization, and Relaxation.

Bayesian View

For a broader perspective it is useful to invoke a Bayesian view. Then the sought parameter vector θ is itself a random vector with a certain pdf. This random vector will of course be correlated with the observations y. If we assume that the *prior distribution* of θ (before y has been observed) is Gaussian with mean θ^* and covariance matrix Π,

$$\theta \in N(\theta^*, \Pi) \qquad (25)$$

its prior pdf is

$$P(\theta) = \frac{1}{\sqrt{(2\pi)^p \det(\Pi)}} e^{-(\theta - \theta^*)^T \Pi^{-1}(\theta - \theta^*)/2} \qquad (26)$$

The posterior (after y has been measured) pdf then is by Bayes rule (Y denoting all measured y signals)

$$P(\theta|Y) = \frac{P(\theta, Y)}{P(Y)} = \frac{P(Y|\theta)P(\theta)}{P(Y)} \qquad (27)$$

In the last step $P(Y|\theta)$ is the likelihood function (cf. the negative log likelihood function $L_N(\theta)$ in (21)), $P(\theta)$ is the prior pdf (26), and $P(Y)$ is a θ-independent normalization. Apart from this normalization, and other θ-independent terms, twice the negative logarithm of (27) equals $W_N(\theta)$ in (24) with

$$\lambda R = \Pi^{-1} \qquad (28)$$

That means that with (28), the regularized estimate from (24) is the *maximum a posteriori* (MAP) estimate. As more and more data become available, the role of the prior will tend to zero, so as $N \to \infty$ the MAP Estimate $\to$ MLE.

This Bayesian interpretation of the regularized estimate also gives a clue to select the regularization quantities λ, R, θ^*.

For black-box models, a reasonable prior (Π, θ^*) may not be available. Then it is possible to parameterize them with *hyperparameters* α and then estimate these through the marginal likelihood:

$$\hat{\alpha} = \arg \max P(Y|\alpha) \qquad (29)$$

A survey of how such techniques may improve system identification techniques is given in Pillonetti et al. (2014).

More aspects of the Bayesian view of system identification are given in ▸ System Identification Techniques: Convexification, Regularization, and Relaxation and in ▸ Nonlinear System Identification Using Particle Filters.

Frequency Domain Data

Frequency domain data are obtained either from frequency analysers or by applying the Fourier transform to measured time domain data. The data could be in the input-output form

$$Y_N(e^{i\omega_k}), U_N(e^{i\omega_k}), \ k = 1, 2, \ldots, M \qquad (30)$$

$$Y_N(z) = \frac{1}{\sqrt{N}} \sum_{k=1}^{N} y(k) z^{-k} \qquad (31)$$

or being observed samples from the frequency function

$$\hat{\hat{G}}_N(e^{i\omega_k}), \ k = 1, 2, \ldots, M \qquad (32)$$

$$\text{e.g., } \hat{\hat{G}}_N(e^{i\omega}) = \frac{Y_N(e^{i\omega})}{U_N(e^{i\omega})} \text{ (ETFE)} \qquad (33)$$

((33) is the *empirical transfer function estimate*, ETFE).

Linear Parametric Models

By taking the Fourier transform of (5a), we see that

$$Y(e^{i\omega}) = G(e^{i\omega}, \theta) U(e^{i\omega}) \qquad (34)$$

plus a noise term that has variance

$$\sigma^2 |H(e^{i\omega}, \theta)|^2 \qquad (35)$$

Simple least squares (LS) curve fitting of (34) says that we should fit observations with weights that are inversely proportional to the measurement variance. That gives the weighted LS criterion

$$V_N(\theta) = \sum_{k=1}^{M} |Y(e^{i\omega_k}) \\ - G(e^{i\omega_k}, \theta) U_N(e^{i\omega_k})|^2 / |H(e^{i\omega_k}, \theta)|^2 \qquad (36)$$

(the constant σ^2 does not affect the minimization of V_N).

It can readily be verified that (36) coincides with (18), $(\ell(\varepsilon) = |\varepsilon|^2)$ by Parseval's identity in case $M = N$ and the frequencies ω_k are selected as the DFT grid.

Notice that (36) can be written as

$$V_N(\theta) = \sum_{k=1}^{M} \left| \frac{Y_N(e^{i\omega_k})}{U_N(e^{i\omega_k})} - G(e^{i\omega_k}, \theta) \right|^2 \\ \cdot \left| \frac{U_N(e^{i\omega_k})}{H(e^{i\omega_k}, \theta)} \right|^2 \qquad (37)$$

We can see that as a properly weighted curve fitting of the frequency function to the ETFE (33).

See ▸ Frequency Domain System Identification for more details of using frequency domain data for estimating dynamical systems.

Nonparametric Methods

From frequency domain data, the frequency response functions $G(e^{i\omega}), H(e^{i\omega})$ can also be estimated directly as functions without any parametric model. See ▸ Nonparametric Techniques in System Identification for a detailed account of this.

IV and Subspace Methods

Instrumental Variables

The family of identification methods that can be described as minimizing a specific criterion function, like (19), covers many theoretically and practically important techniques. Still, several methods do not belong to this family. A useful

S

technique is to characterize a good model, as one that gives prediction errors that are uncorrelated with available information:

$$\hat{\theta} = \mathrm{sol}_{\theta \in D_{\mathcal{M}}} \sum_{t=1}^{N} \varepsilon(t, \theta)\zeta(t, \theta) = 0 \qquad (38)$$

Here, $\varepsilon(t, \theta)$ is the prediction error (16), and sol means "solution to." The sequence $\{\zeta(t), t = 1, \ldots, N\}$ is constructed from the observed data, possibly also dependent on some design variables that are included in θ. Typically $\zeta(t)$ is constructed from past inputs, so a good model should not have prediction errors that are correlated with past observations. The variables ζ are called *instrumental variables*, and there is an extensive literature about how to select these. See, e.g., Ljung (1999), Section 7.5, Söderström and Stoica (1983), and Young (2011).

Subspace Methods

A related technique is to estimate black-box state-space models like (12) (without any internal parametric structure) by realizing the states from data and then estimating the matrices by least squares method. This gives a powerful family of methods for state-space model estimation. They are described in detail in ▶ Subspace Techniques in System Identification. The major advantage of subspace methods is that they easily apply to multiple-input-multiple-output systems and are non-iterative. A drawback is that the model properties and their dependence on certain design variables are not fully known.

Errors-in-Variables (EIV) Techniques

The estimation techniques described so far assume that the input has been measured without errors. In some cases, it is natural to assume that both inputs and outputs have measurement errors. The estimation problem then becomes more difficult, and some kind of knowledge about the measurement errors is typically required. In Pintelon and Schoukens (2012), Section 8.2, it is described how criteria of the type (36) are modified in the presence of input noise, and Söderström (2007) can be consulted for a summarizing treatise on EIV techniques. See also the section "Errors-in-Variables Framework" in ▶ Frequency Domain System Identification.

Asymptotic Properties of the Estimated Models

An estimated model is useless, unless something is known about its reliability and error bounds. Therefore, it is important to analyze the model properties.

Bias and Variance

The observations, certainly of the output from the system, are affected by noise and disturbances, which of course also will influence the estimated model parameters (19). The disturbances are typically described as stochastic processes, which makes the estimate $\hat{\theta}_N$ a *random variable*. This has a certain pdf and often the analysis is restricted to its mean and variance only. The difference between the mean and a true description of the system measures the *bias* of the model. If the mean coincides with the true system, the estimate is said to be *unbiased*. The total error in a model thus has two contributions: the bias and the variance.

Properties of the PEM Estimate (19) as $N \to \infty$

Except in simple special cases, it is quite difficult to compute the pdf of the estimate $\hat{\theta}_N$. However, its *asymptotic properties* as $N \to \infty$ are easier to establish. The basic results can be summarized as follows (E denotes mathematical expectation; see Ljung (1999), chapters 8 and 9, for a more complete treatment):

- **Limit Model:**

$$\hat{\theta}_N \to \theta^*$$

$$= \arg\min \left[\lim_{N \to \infty} \frac{1}{N} V_N(\theta) \approx \mathrm{E}\ell(\varepsilon(t, \theta)) \right] \tag{39}$$

So the estimate will converge to the best possible model, in the sense that it gives the smallest average prediction error.

- **Asymptotic Covariance Matrix for Scalar Output Models:**
  In case the prediction errors $e(t) = \varepsilon(t, \theta^*)$ for the limit model are approximately white, the covariance matrix of the parameters is asymptotically given by:

$$\text{Cov}\hat{\theta}_N \sim \frac{\kappa(\ell)}{N} \left[\text{Cov} \frac{d}{d\theta} \hat{y}(t|\theta) \right]^{-1} \quad (40)$$

So the covariance matrix of the parameter estimate is given by the inverse covariance matrix of the gradient of the predictor wrt the parameters. Here (prime denoting derivatives)

$$\kappa(\ell) = \frac{E[\ell'(e(t))]^2}{E\ell''(e(t))^2} \quad (41)$$

Note that

$$\kappa(\ell) = \sigma^2 = Ee^2(t) \quad \text{if } \ell(e) = e^2/2$$

If the model structure contains the true system, it can be shown that this covariance matrix is the smallest that can be achieved by any unbiased estimate, in case the norm ℓ is chosen as the logarithm of the pdf of e. That is, it fulfills the *the Cramér-Rao inequality* (Cramér 1946). These results are valid for quite general model structures. Now, specialize to linear models (5a) and assume that the true system is described by

$$y(t) = G_0(q)u(t) + H_0(q)e(t) \quad (42)$$

which could be general transfer functions, possibly much more complicated than the model. Then

- $$\theta^* = \arg\min_{\theta} \int_{-\pi}^{\pi} |G(e^{i\omega}, \theta) - G_0(e^{i\omega})|^2$$
  $$\frac{\Phi_u(\omega)}{|H(e^{i\omega}, \theta)|^2} d\omega \quad (43)$$

That is, the frequency function of the limiting model will approximate the true frequency function as well as possible in a frequency norm given by the input spectrum Φ_u and the noise model.

- For a linear black-box model

$$\text{Cov}G(e^{i\omega}, \hat{\theta}_N) \sim \frac{n}{N} \frac{\Phi_v(\omega)}{\Phi_u(\omega)} \text{ as } n, N \to \infty \quad (44)$$

where n is the model order and Φ_v is the noise spectrum $\sigma^2|H_0(e^{i\omega})|^2$. The variance of the estimated frequency function at a given frequency is thus, for a high-order model, proportional to the noise-to-signal ratio at that frequency. That is a natural and intuitive result.

Trade-Off Between Bias and Variance

Generally speaking the quality of the model depends on the quality of the measured data and the flexibility of the chosen model structure (3). A more flexible model structure typically has smaller bias, since it is easier to come closer to the true system. At the same time, it will have a higher variance: With higher flexibility it is easier to be fooled by disturbances. So the trade-off between bias and variance to reach a small total error is a choice of balanced flexibility of the model structure.

As the model gets more flexible, the fit to the estimation data in (19), $V_N(\hat{\theta}_N)$, will always improve. To account for the variance contribution, it is thus necessary to modify this fit to assess the total quality of the model. A much used technique for this is Akaike's criterion, (AIC) (Akaike 1974):

$$\hat{\theta}_N = \arg\min_{\mathcal{M}, \theta \in D_{\mathcal{M}}} 2L_N(\theta) + 2\dim\theta \quad (45)$$

where L_N is the negative log likelihood function. The minimization also takes place over a family of model structures with different number of parameters (dim θ).

For Gaussian innovations e with unknown and estimated variance, AIC takes the form

$$\hat{\theta}_N = \underset{\mathcal{M}, \theta \in D_{\mathcal{M}}}{\arg\min} \left[\log \det \left[\frac{1}{N} \sum_{t=1}^{N} \varepsilon(t, \theta) \varepsilon^T(t, \theta) \right] + 2 \frac{\dim \theta}{N} \right] \tag{46}$$

after normalization and omission of model-independent quantities.

A variant of AIC is to put a higher penalty on the model complexity:

$$\hat{\theta}_N = \arg\min \left[2L_N(\theta) + \dim \theta \log N \right] \tag{47}$$

This is known as Bayesian information criterion (BIC) or Rissanen's minimum description length (MDL) criterion (Rissanen 1978).

Section "$\mathcal{V}$: Model Validation" contains further aspects on the choice of model structure.

$\mathcal{X}$: Experiment Design

Experiment design is the question of choosing which signal to measure, the sampling rate, and designing the input.

The theory of experiment design primarily relies upon analysis of how the asymptotic parameter covariance matrix (40) depends on the design variables: so the essence of experiment design can be symbolized as

$$\min_{\mathcal{X}} \text{trace}\{C[E\psi(t)\psi^T(t)]^{-1}\}$$

where ψ is the gradient of the prediction wrt the parameters and the matrix C is used to weight variables reflecting the intended use of the model.

For linear systems the input design is often expressed as selecting the spectrum (frequency contents) of u.

This leads to the following recipe: Let the input's power be concentrated to frequency regions where a good model fit is essential and where disturbances are dominating.

Issues of experiment design are treated in much more detail in ▸ Experiment Design and Identification for Control.

The measurement setup, like if band-limited inputs are used to estimate continuous-time models and how the experiment equipment is instrumented with band pass filters (see, e.g., Pintelon and Schoukens 2012, Sections 13.2–3), also belongs to the important experiment design questions.

$\mathcal{V}$: Model Validation

Model validation is about examining and scrutinizing an estimated model to check if it can be used for its purpose. These methods unavoidably are problem dependent and contain several subjective elements, and no conclusive procedure for validation can be given. A few useful techniques will be listed in this section. Basically it is a matter of trying to falsify a model under the conditions it will be used for and also to gain confidence in its ability to reproduce new data from the system.

Falsifying Models: Residual Analysis

An estimated model is never a correct description of a true system. In that sense, a model cannot be "validated." Instead it is instructive to try and *falsify* it, i.e., confront it with facts that may contradict its correctness. A good principle is to look for the *simplest unfalsified model*; see, e.g., Popper (1934).

Residual analysis is the leading technique for falsifying models: The residuals, or one-step-ahead prediction errors $\hat{\varepsilon}(t) = \varepsilon(t, \hat{\theta}_N) = y(t) - \hat{y}(t|\hat{\theta}_N)$ should ideally not contain any traces of past inputs or past residuals. If they did, it means that the predictions are not ideal. So, it is natural to test the correlation functions

$$\hat{r}_{\hat{\varepsilon},u}(k) = \frac{1}{N} \sum_{t=1}^{N} \hat{\varepsilon}(t+k)u(t) \qquad (48)$$

$$\hat{r}_{\hat{\varepsilon}}(k) = \frac{1}{N} \sum_{t=1}^{N} \hat{\varepsilon}(t+k)\hat{\varepsilon}(t) \qquad (49)$$

and check that they are not larger than certain thresholds. Here N is the length of the data record and k typically ranges over a fraction of the interval $[-N\,N]$. See, e.g., Ljung (1999), Section 16.6 for more details.

Comparing Different Models
When several models have been estimated, it is a question to choose the "best one." Then, models that employ more parameters naturally show a better fit to the data, and it is necessary to outweigh that. The model selection criteria AIC (46) and BIC (47) are examples of how such decisions can be taken. They can be extended to regular hypothesis tests where more complex models are accepted or rejected at various test levels (Ljung 1999, Sect. 16.4).

Making comparisons in the frequency domain is a very useful complement for domain experts who are used to think in terms of natural frequencies, natural damping, etc.

Cross Validation
Cross validation is an important statistical concept that loosely means that the model performance is tested on a data set (*validation data*) other than the estimation data. There is an extensive literature on cross validation, e.g., Stone (1977), and many ways to split up available data into estimation and validation parts have been suggested. A simple way, often used in system identification, is to use one-half of the data to estimate the model and the other half to evaluate simulation or prediction fit. Trying out different model structures (or other decision variables, like regularization parameters), one then picks the choice that gives the best performance on validation data.

Other Topics

Numerical Algorithms and Software Support
The central numerical task to estimate the model lies in the innocent-looking "arg min" in (38). Since the criterion often is non-convex, this global minimization can be nontrivial. Typically some iterative numerical optimization method, like Gauss-Newton, Levenberg-Marquardt, or trust regions, e.g., Nocedal and Wright (2012), is employed. The iterations are initiated at a carefully selected point, for black-box linear systems often based on ARX or subspace estimates.

The practical use of system identification relies upon efficient software support. Many such packages exist. They are further treated along with numerical and computational aspects in ▶ System Identification Software.

Estimating Continuous-Time Models
Most of the techniques described here formally seem to deal with estimating discrete time model. However continuous-time (CT) models are to be preferred in many contexts, and most of the modeling of physical systems really concern CT models. A natural approach is to do physical modeling in continuous time as in (11) and then do estimation of the CT matrices via the sampled model (12). All the described algorithms and results apply to this approach to CT model estimation. Another approach is to use band-limited inputs and compute the CT Fourier transforms of data (that coincide with the discrete time transforms for band-limited data) and apply ▶ Frequency Domain System Identification.

Yet another approach is to directly fit CT model parameters to discrete time data, using specially designed filters; see, e.g., Garnier and Wang (2008).

Recursive Estimation
For certain adaptive and in-line applications, it may be necessary to continuously compute the models by recursively updating the estimates. The techniques for that resemble state-estimation

algorithms and are dealt with in a general setting in ▶ Nonlinear System Identification Using Particle Filters. See also Ch 11 in Ljung (1999).

Data Management

The collected data often requires particular attention before it can be used for estimation. Issues like missing observations, obviously erroneous values (outliers), slowly varying disturbances, trends, etc., need attention. In industrial applications, a practical question is often to select portions of the data records that contain relevant information for the model building. Such questions are application dependent and related to experiment design and also to database management. Some techniques for preparing data for identification are mentioned in Ch 14 of Ljung (1999).

Summary and Future Directions

System identification is a mature and well-established area in automatic control. The methods are successfully and routinely applied in industrial practice, and the understanding of theoretical issues is mostly excellent. The standard theory relies very much on basic statistical concepts and methods.

What is exciting about future development is what increased computation power may mean for the area: Can nonlinear models be efficiently estimated by massive computational efforts? Will tools inspired by machine learning turn out to be superior to the conventional approaches? Can reliable uncertainty regions be computed for arbitrary noises and without the asymptotic formulas?

Several of these questions are illuminated in the articles listed under Cross-References.

Cross-References

There are several articles in this encyclopedia that deal with aspects of system identification. They have been coordinated with this overview and the text has listed how they complement the

issues treated here. For easy reference, here is a complete list of associated articles:

Tactical Missile Autopilots

Curtis P. Mracek
Raytheon Missile Systems, Waltham, MA, USA

Abstract

Tactical missile autopilots are part of the wider guidance navigation and control missile system whose goal is to achieve a successful intercept. The missile autopilot task is to turn guidance commands into fin deflection and is generally divided into two lateral direction (pitch and yaw) controllers and the roll orientation or roll rate controller. These three "channel control" outputs are then mixed to produce fin commands. The controllers can be composed of different architectures but most lateral autopilots use a three loop structure with acceleration and angular rate feedback. The roll controller is usually either a proportional integral (PI) or proportional integral derivative (PID) controller. The controllers are designed using gain scheduling for large flight envelope applications and have nonlinear elements to shape the time response. Integrator reset logic, to deal with control surface saturation, is also an integral part of tactical missile autopilots.

Keywords

Classical control; Control surfaces; Pitch; Proportional and integral control; Roll channel; Tactical missile; Yaw channels

Introduction

The purpose of a tactical missile is to intercept targets, and since tactical missile autopilots are part of the larger tactical missile system, they must contribute to that goal. The process by which a missile executes an intercept is by first sensing the target. The target information is then used to generate guidance commands. The guidance commands are determined such that if followed with precision the missile will intercept the target. The problem is to follow with precision. This is where the autopilot comes in. The missile autopilot receives guidance commands and produces control deflections to move the missile in a manner consistent with completing the intercept. There are many control challenges unique to tactical missiles, namely closing velocities can be very high and targets very small and very maneuverable. Usually the guidance commands are acceleration commands though other quantities are sometimes used. For this discussion, acceleration commands will be the autopilot

commands. Once the acceleration commands or demands (as some in the guidance community call the autopilot inputs) are presented to the autopilot, the autopilot's only concern is to produce the desired command as fast as possible with some level of robustness. The key performance metric is the time of response. The response time is a key factor that drives the miss distance, and thus the probability of a successful intercept. Another metric, though less important than the response time, is the available maneuverability. As mentioned, the autopilot achieves the desired acceleration through moving the control surfaces. Usually, the control surfaces are aerodynamic and either positioned in front of (canard control) or in back of (tail control) the center of gravity. Both tail and canard control surfaces will be called fins for the purposes of this analysis. Some recent missile designs have significantly altered the autopilot design problem by using both canards and tails or other effectors like reaction jets.

The tactical missile autopilot control problem is therefore to produce accelerations by moving the fins in a controlled manner such that the response is as fast as possible while remaining under control under various flight conditions and in the presence of uncertainties (being robust). Tactical missiles autopilots are a classic control challenge in that there is a direct trade between performance and robustness. The tactical autopilot tends to lean toward the performance instead of the robustness because, as the continuing argument goes, "what good is the missile being stable if you miss the target" versus "if the missile is unstable it may never get to the target." So far, relevant analysis has mentioned the controller but mostly ignored robustness. Achieving robustness is done through the use of feedback, and in tactical missiles, inertial sensing devices are used to provide this critical information. These tactical sensors are currently packaged as a complete inertial sensor suite. This suite usually consists of three orthogonal linear accelerometers and three angular rate gyros. One reason guidance commands are the linear acceleration is that the sensing device directly measures this desired quantity.

There are two noticeable differences between tactical missile control and other aerodynamic control applications. The first is that the dynamics and controls are divided into three distinct channels with each channel nearly independent of the other two. These are the lateral (pitch and yaw) channels and the axial (roll) channel. The pitch and yaw designs are usually very similar, if not identical, and the roll channel is separate. The second is that the controllers (fins) are intertwined. That is, there are no predominately pitch, yaw, or roll controllers, such as there are on airplanes. At least two and sometimes four fins are used in a single channel. This mixing of controls is through what is called a fin mix. This fin mixing occurs in the software (used to be hardware in analog controllers) after the autopilot and prior to the signals being sent to the individual fins.

Historically tactical missile autopilot development has consisted of both a design phase and an analysis phase. This distinction is due to the controller being designed on a subset of the operating envelope. That design is then evaluated at many more conditions to determine if the design works well enough everywhere to be deployed. In both the design and analysis phases, models are used to establish performance and robustness. Linear planar, linear coupled, and nonlinear models are used. The linear models are usually restricted to the early design phases and the frequency response determination of the system. The nonlinear models are used for time domain analysis.

The remainder of the chapter is organized by examining the linear planar pitch and yaw autopilots, followed by roll control. The concept of combining controllers is then presented. This is followed by a short section on other considerations, such as coupled designs and nonlinear elements.

Pitch and Yaw Control

For tactical missile autopilot development, the equations of motion are usually derived in a body-fixed system with the two lateral velocities replaced by the local angle of attack (α) and sideslip angle (β). It should be noted that the

sideslip is not defined as the aircraft sideslip but instead as the equivalent of the angle of attack in the horizontal plane. This is because of the symmetry that is found in missiles that does not exist in aircraft. The nonlinear equations of motion can be found in Blakelock (1991). For tactical missiles there is usually no axial acceleration control, and thus the total velocity equation is uncontrollable and removed from both the design and analysis. For the coupled equations of motion of the system, there are five equations of motion and three control inputs. For a planar view of the problem, the pitch and yaw channels in a tactical missile autopilot are usually separated, and with the appropriate sign changes in the feedback signals can use the same gains. These channels use an inertial measuring device for feedback. Usually these sensors come in a package with three accelerometers and the gyros. The outputs of these devices used in the pitch are the linear acceleration perpendicular to the axial direction and the angular rate of the missile about the other perpendicular axis. That is, the z linear acceleration (A_{zm}) and the y angular rate (q_m). Using the other four sensors would cause coupling between pitch and yaw and roll, and thus this sensor information is usually ignored in the pitch channel. They are available and used in select cases where there is strong aerodynamic coupling, in which case these cross channels can be used to decouple the system. Without getting into the actual definitions of all the variables and the numerical values (see Mracek and Ridgely 2005a for full details), the state space linearized equations of motion for the pitch plane are:

$$A = \begin{bmatrix} 1/V_{mo}\left[\frac{Z_{\alpha o}}{m} - A_{Xo}\right] & 1 \\ M_{\alpha o}/I_{YY} & 0 \end{bmatrix}$$

$$B = \begin{bmatrix} Z_{\delta po}/mV_{mo} \\ M_{\delta po}/I_{YY} \end{bmatrix}$$

$$C = \begin{bmatrix} Z_{\alpha o}/mg - M_{\alpha o}\bar{x}/gI_{YY} & 0 \\ 0 & 1 \end{bmatrix}$$

$$D = \begin{bmatrix} Z_{\delta po}/mg - M_{\delta po}\bar{x}/gI_{YY} \\ 0 \end{bmatrix}$$

where

$$\dot{x} = Ax + Bu \quad x = \begin{bmatrix} \alpha \\ q \end{bmatrix} \quad u = \delta_p \quad y = \begin{bmatrix} A_{zm} \\ q_m \end{bmatrix}$$
$$y = Cx + Du$$

Thus in the most reduced form, the tactical missile autopilot equations of motion reduce to two equations with two variables and one control. This is a very simple control problem. Since full state feedback can be used to provide an "optimal" control solution, only two feedback signals are needed for the above state space problem. For a tail controlled missile, the two state control leads ultimately to increasing missile acceleration in the wrong direction, as faster and faster designs are realized. This is because the system is, in controls language, "non-minimum phase." That is, tail controlled missiles move in the wrong direction before they move in the commanded direction. Canard controlled missiles do not suffer this problem. See Mracek (2005) and Gutman (2003) on the relative merits of canards and tails. If the control rate is used as the input instead of the control position, there would be three states in the basic plant used in the analysis, and three signals would need to be included. Now if we consider the fin position as a variable for feedback with the accelerometer and gyro feedbacks, there are a number of different combinations of sensor feedback signals that can be used to solve the three state problem. There are, in fact, nine possible topologies, two of which are consistently robust, with one topology showing excellent robustness characteristic. For a complete comparison see Mracek and Ridgely (2005b). This topology is shown in Fig. 1. Notice that there is an integral in the formulation. This limits the actual command rate from being infinite when a step command is input to the system. Without the command going through the integrator the controller would see the step, and, since the force instantly produces an acceleration, the feedback would jump (given no actuation delay). A typical acceleration response to a step acceleration command and control deflection rate needed to produce the response is presented in Figs. 2 and 3, respectively.
Tactical Missile Autopilots, Fig. 1 Three loop pitch topology
Tactical Missile Autopilots, Fig. 2 Acceleration response to a step input
Tactical Missile Autopilots, Fig. 3 Control rate usage

The feedback control law is:

$$\delta_p = K_{IA_z}K_{ss} \int A_{Z_c} dt - K_{IA_z} \int A_{Z_m} dt$$

$$+ K_\theta \int q_m dt + K_q qm$$

Clearly, other components within the autopilot loop have to be considered. The control actuation system (CAS) and inertial measurement device characteristics need to be included in the design and synthesis of the autopilot. To this end, the gains are usually selected to provide the best performance (in the time domain) based on constraints. The above optimal control solution provides guaranteed margins, but when the additional components are included in the analysis the margins are an important constraint in the ultimate performance that can be achieved. Like most control problems, the constraints are both time and frequency dependent. Because of the emphasis on performance, some of the margin constraints must be examined closely. For a more detailed treatment of the three loop autopilot see Zarchan (2002).

Roll Control

Thus far we have discussed the two lateral channels of the missile. That is because those two are the channels that directly affect the miss distance. The third channel does not directly influence the miss but it still is usually controlled. The roll channel is usually the fastest of the channels for a tactical missile. Historically, the three channels were decoupled by moving the roll "out of the

way" of the other channels by designing to a higher bandwidth than the pitch and yaw channels. Because of the need for squeezing performance this practice is not always employed. The cost of not increasing the bandwidth of the roll beyond the pitch and yaw is that the interdependence of the channels needs more scrutiny. The roll channel has only one sensor element, the roll rate senor. This measures the angular rate of the body about its central axis relative to the inertial frame. The objective, and thus the autopilot, can differ depending on the missile application. Mostly the objective would be one of the following: maintain zero roll rate, zero integral of roll rate, or some preferred Euler angle orientation. The last two can be accomplished with the same autopilot architecture, with exception handling for the Euler roll control based on the singularity in the Euler roll angle at ±90° pitch orientations.

Since there is only one sensor and one control, this channel is a classical SISO system and can be controlled with a proportional derivative (PD) or proportional integral derivative (PID) controller. The three loop topologies with integral roll rate reference are presented in Fig. 4.

Gain Scheduling

Early generation missiles had analog autopilots and some were marvels of ingenuity. Now digital control is used almost exclusively. As can be readily seen from the above discussion, the autopilots performance is largely dictated by gains within a given topology. Unlike with early autopilots, with digital control the gains can be set precisely and can vary greatly as needed

Tactical Missile Autopilots, Fig. 4 Three loop roll topology
over a wide range of flight conditions. Rarely can a single set of gains be found that provides adequate performance under all conditions. Thus, the autopilot design process is to design for a large number of flight conditions and then join the individual designs into a coherent whole. Typically, the conditions for the individual designs would be something like Mach number, altitude, and center of mass location. Once the individual gains are designed, they are joined together through an algorithm. Most likely they are "looked up" as a continuous function of the independent variables through some sort of interpolation. This gain changing philosophy is called gain scheduling. There have been some successful attempts for full envelope autopilot design. Dynamic inversion or model-based approaches have also been developed, most notably JDAM (Wise et al. 2005) where the autopilot was borrowed and adjusted on the fly from a sister design. The argument for the validity of this approach is that the flight conditions are not changing rapidly so they can be ignored. Of course the synthesis of the design needs to include examination of "off break point" conditions (flight conditions within the flight envelope that were not considered in the design process) to ensure compliance with stability requirements. History has shown that tactical missile autopilot gains tend to be somewhat power functions of dynamic pressure based on the design constraints.

Other Considerations

The selection of gains using planar linear models and then scheduling them is not the complete autopilot design exercise. There are other challenges that must be considered. First, the plant equations are coupled through both the kinematic equations and the aerodynamics of the problem. There are two predominant ways to attack this problem in autopilot design. The first is as discussed earlier in which the system is made to be as decoupled as possible, create gains for the decoupled system and analyze them in the coupled system. The second is to use feedback to create a more integrated design through cross coupling terms.

Besides the coupling there can be other problems. The design problem is hard enough as described above, but we have learned over the years that the models developed earlier have neglected certain aspects of the missile that can lead to problems. One aspect is that missiles can be very flexible, and since an inertial sensor is being used for feedback, the flexible characteristics can drive the missile unstable. The flexible characteristics were examined by Nesline and Nesline (1985). In that paper, the flexible model is presented and a technique for ignoring the first mode is discussed. (It should be noted that the model presented in the appendix has some "typos" and should be used with caution.)

Another aspect is the consideration of nonlinear elements of the autopilot. These could include integrator reset logic, command error limits, and acceleration limits. The three loop autopilot has an integrator and the fact that integrators "wind up" when the output is saturated. For tactical missiles this saturation could be caused by position or rate limits. The integrator should be reset to account for these conditions so that the missile responds quicker when the system is no longer in a saturated condition. The command error limits can be used to modify the response characteristics to achieve a more consistent response. Finally, acceleration limits are used to limit the input into the system such that the guidance commands do not put the missile into a position from which it cannot maintain controlled flight. Generating acceleration limits is a complex topic itself.

Summary and Future Directions

Tactical missile autopilots are generally designed by separating the problem into two independent

lateral controls (pitch and yaw), with a third control governing the roll attitude. A good autopilot design produces a balance between performance and robustness and incorporates nonlinear elements and integrator resets. The design process take into account robustness throughout the flight envelope and structural elements.

From a controls standpoint, the future direction of tactical missile autopilot development is in nonlinear, adaptive, and fault tolerant control. Adaptive control is useful not only because it provides a more predictable flight response but also because of the potential in reducing or maybe even eliminating development time.

Time-Scale Separation in Power System Swing Dynamics: Singular Perturbations and Coherency

Joe H. Chow
Department of Electrical and Computer Systems Engineering, Rensselaer Polytechnic Institute, Troy, NY, USA

Abstract

Large power systems often exhibit slow and fast electromechanical oscillations between interconnected synchronous machines. The slow interarea oscillations involve coherent groups of machines swinging together. This coherency phenomenon can be attributed to the coherent areas of machines being weakly coupled, either because of higher impedance transmission lines, heavily loaded transmission lines, or fewer connections between the coherent areas compared to the connections within a coherent area. Singular perturbations can be used to display the time-scale separation of the slow interarea modes and the faster local modes.

Keywords

Model reduction; Power system oscillations; Singular perturbations; Two-time-scale systems

Interarea Mode Oscillation in a Power System

A large power system consists of interconnected synchronous machines supplying power to loads via transmission lines. As a dynamical system, it can be considered as the rotating inertias of the synchronous machines interacting electrically through the impedances of the transmission system. During a disturbance, such as a lightning strike on a transmission line, the rotating inertias will oscillate against each other. The frequency and extent of these oscillations
Time-Scale Separation in Power System Swing Dynamics: Singular Perturbations and Coherency, Fig. 1 Two-area, four-machine system example

Time-Scale Separation in Power System Swing Dynamics: Singular Perturbations and Coherency, Fig. 2 Machine speed response of the two-area, four-machine system
may vary: the local modes of frequencies 1–2.5 Hz originate from the interactions of a few close-by machines, and the interarea modes of frequencies 0.2–0.8 Hz involve groups of machines swinging against other groups. Coherency is this phenomenon of groups of machines swinging together against other groups of machines during disturbances.

Coherency can be illustrated in the simple power system shown in Fig. 1 (Rogers 2000). The system consists of two areas: Generators 1 and 2 in Area 1 and Generators 11 and 12 in Area 2. For a disturbance in Area 1, Fig. 2 shows the response of the machine speeds. The interarea mode consists of Generators 1 and 2 swinging coherently against Generators 11 and 12. The

difference between the responses of Generators 1 and 2 is due to the local mode in Area 1, which is excited by the disturbance.

Coherency Analysis

Coherency with respect to the slow interarea modes, also known as slow coherency, is an inherent property of many power systems. Traditional power systems consist of operating regions dictated by physical or administrative constraints with relatively strong connections within an operating region. These control regions are also interconnected with tielines to share base-load and seasonal power resources as well as to rely on

each other for reserves. Thus a practical interconnected power system will, by design, necessarily have strong connections within each operating region and weaker connections between the regions. Due to the time-scale separation of the slow interarea modes and the faster local modes, the coherency phenomenon can be analyzed using singular perturbations method provided a suitable small parameter can be identified.

For a simplified coherency analysis, the linearized second-order model of an N-machine power system

$$M \frac{d^2 \Delta \delta}{dt^2} = K \Delta \delta \qquad (1)$$

can be used. In (1), δ is the N-dimensional vector of individual machine rotor angles δ_i, $i = 1, \ldots, N$, Δ denotes small perturbations, M is the diagonal matrix of machine rotational inertias m_i, $i = 1, \ldots, N$, and the *connection matrix K* consists of the linearized synchronizing coefficients K_{ij} between machines i and j, denoting the restoring force between the two machines.

An important property of K is

$$K_{ii} = - \sum_{j=1, j \neq i}^{N} K_{ij} \qquad (2)$$

that is, the sum of each row of K is zero. Thus K has a zero eigenvalue, which is known as the system mode. This mode arises due to the lack of a reference, as only the relative angles between the machines are important. It can be eliminated when one of the machines is chosen as the reference.

Suppose the N-machine system has r areas of coherent machines, whose internal connections within the areas are stronger than the external connections between the areas. The weak connection strength is denoted by a small parameter ε, which can be the ratio of the relative stiffness of the internal transmission lines versus the external transmission lines, or the ratio of the smaller number of external connections versus the larger number of internal connections, or both. Thus the connection matrix of linearized synchronizing coefficients can be rewritten as

$$K = K^I + \varepsilon K^E \qquad (3)$$

where K^I is the matrix of internal connections and K^E is the matrix of external connections scaled by ε. If the machine angles in each coherent area are arranged in consecutive order in the vector δ, then K^I is block diagonal with r zero eigenvalues, that is, one system mode per area.

Singular Perturbation Analysis

To exhibit the time scales in (1) and (3), a transformation to obtain the slow variables and the fast variables is introduced. The slow motion is obtained by defining for each area, an inertia-weighted *aggregate variable*

$$y^\alpha = \sum_{i=1}^{n_\alpha} m_i^\alpha \Delta \delta_i^\alpha / m^\alpha,$$

$$m^\alpha = \sum_{i=1}^{n_\alpha} m_i^\alpha, \quad \alpha = 1, 2, \ldots, r \qquad (4)$$

where n_α is the number of machines in area α, m_i^α is the inertia of machine i in area α, and m^α is the aggregate inertia of area α. For the fast dynamics, we select in each area a reference machine, say the first machine, and define the motions of the other machines in the same area relative to this reference machine by the *local variables*

$$z_{i-1}^\alpha = \Delta \delta_i^\alpha - \Delta \delta_1^\alpha, \quad i = 2, 3, \ldots, n_\alpha,$$

$$\alpha = 1, 2, \ldots, r \qquad (5)$$

The transformations (4) and (5) can be combined to form

$$\begin{bmatrix} y \\ z \end{bmatrix} = \begin{bmatrix} M_a^{-1} U^T M \\ G \end{bmatrix} \Delta \delta \qquad (6)$$

where

$$U = \text{blockdiag}(u_1, u_2, \ldots, u_r) \qquad (7)$$

is the grouping matrix with $n_\alpha \times 1$ column vectors

$$u_\alpha = \begin{bmatrix} 1 \ 1 \ \ldots \ 1 \end{bmatrix}^T, \quad \alpha = 1, 2, \ldots, r \quad (8)$$

$$M_a = \mathrm{diag}(m^1, m^2, \ldots, m^r) = U^T M U \quad (9)$$

and

$$G = \mathrm{blockdiag}(G_1, G_2, \ldots, G_r) \quad (10)$$

with G_α being the $(n_\alpha - 1) \times n_\alpha$ matrix

$$G_\alpha = \begin{bmatrix} -1 & 1 & 0 & . & 0 \\ -1 & 0 & 1 & . & 0 \\ . & . & . & . & . \\ -1 & 0 & 0 & . & 1 \end{bmatrix} \quad (11)$$

The inverse of this transformation is explicitly known

$$\Delta\delta = \begin{bmatrix} U \ G^T(GG^T)^{-1} \end{bmatrix} \begin{bmatrix} y \\ z \end{bmatrix} \quad (12)$$

Applying the transformation (6) to the model (1) and (3), the electromechanical model becomes

$$M_a\ddot{y} = \varepsilon K_a y + \varepsilon K_{ad} z$$
$$M_d\ddot{z} = \varepsilon K_{da} y + (K_d + \varepsilon K_{dd}) z \quad (13)$$

where

$$M_d = (GM^{-1}G^T)^{-1}, \quad K_a = U^T K^E U$$

$$K_{da} = U^T K^E M^{-1} G^T M_d,$$

$$K_{da} = M_d G M^{-1} K^E U$$

$$K_d = M_d G M^{-1} K^I M^{-1} G^T M_d,$$

$$K_{dd} = M_d G M^{-1} K^E M^{-1} G^T M_d \quad (14)$$

Note that K_a, K_{ad}, and K_{da} are independent of the internal connection matrix K^I because $K^I U = 0$. Furthermore, K_a is negative semi-definite and K_{dd} is negative definite. System (13) is in the *standard singularly perturbed form* (Kokotović et al. 1986) showing that y is the slow variable and z is the fast variable. Thus ε is both the weak connection parameter and the singular perturbation parameter, giving rise to slow coherency.

The dynamics of the singularly perturbed system (13) are approximated by the interarea modes $\pm j\sqrt{-\varepsilon\lambda(M^{-1}K_a)}$ and the local modes $\pm j\sqrt{-\lambda(M_d^{-1}K_{dd})}$, where λ denotes eigenvalues.

Identifying Coherent Areas

Several methods can be used to identify coherent areas, including the following:

1. Time simulation method (Podmore 1978): This method simulates the dynamic responses to a selected set of disturbances and groups the machines having similar time responses as coherent areas. For a faster simulation, a linearized power system model can be used.
2. Eigenvector method (Chow et al. 1982): This method computes the slow eigenvalues of the matrix $M^{-1}K$ and identifies machines with similar row vectors of the slow eigenvector matrix as coherent machines.
3. Weak link methods (Nath et al. 1985; Zaborszky et al. 1982): These methods search through the transmission line impedances to find the weak links between the areas.

Applications

The applications of the coherency concept include:

1. Dynamic model reduction (deMello et al. 1975): The synchronous machines in a coherent area can be aggregated into a single equivalent machine, thus reducing the system size. Model reduction programs capable of handling upwards of 30,000 buses are available (Morison and Wang 2013).
2. Interarea mode analysis and damping control design (Larsen et al. 1995): Damping of interarea modes is an operational concern for systems with heavily loaded long-distance transmission lines. The slow coherency concept contributes to the development of damping controller design.

3. Islanding as a defense mechanism (You et al. 2004): During system disturbances causing severe power flow interruption, the last resort may be to separate the systems into viable islands, avoiding a total system blackout. Coherent areas tend to be natural choices of islands.

In addition to power system analysis, the coherency concept and methods can potentially be applied to dynamic systems with a system mode (eigenvalue equal to 0 for a continuous-time model and eigenvalue equal to 1 for a discrete-time model). An example is the PageRank computation in (Ishii et al. 2012).

T

Abstract

Tracking and regulation refer to the ability of a control system to track/reject a given family of reference/disturbance signals modelled as solutions of a differential/difference equation. The problem can be posed as a stabilization problem with a constraint on the steady-state response of the system. For linear, time-invariant, systems, the problem can be solved provided a system of linear matrix equations admits a

solution. Properties of this system of equations are discussed, together with a general property of all controllers achieving tracking and regulation: the so-called internal model principle.

Keywords

Internal model principle; Linear systems; Regulation; Tracking

Introduction

Consider a linear system affected by disturbances and such that its output is required to asymptotically track a certain, prespecified, reference signal. In what follows, we discuss and solve this control problem known as the *tracking and regulation problem*.

Consider a linear control system described by equations of the form

$$\sigma x = Ax + Bu + Pd,$$
$$e = Cx + Qd, \tag{1}$$

with $x(t) \in \mathbb{R}^n$, $u(t) \in \mathbb{R}^m$, $e(t) \in \mathbb{R}^p$, $d(t) \in \mathbb{R}^r$, and A, B, P, C, and Q constant matrices. In Eq. (1), $\sigma x = \sigma x(t)$ stands for $\dot{x}(t)$, if the system is continuous-time, and for $x(t + 1)$, if the system is discrete-time. Since the system is time-invariant, it is assumed, without loss of generality, that all signals are defined for $t \geq 0$, that is, if the system is continuous-time, then $t \in \mathbb{R}^+$, i.e., the set of nonnegative real numbers, whereas if the system is discrete-time, then $t \in \mathbb{Z}^+$, i.e., the set of nonnegative integers. For ease of notation, the argument "t" is dropped whenever this does not cause confusion, and we use the notation $t \geq 0$ to denote either $\mathbb{R}^+$ or $\mathbb{Z}^+$.

The signal $d(t)$, denoted exogenous signal, is in general composed of two components: the former models a set of disturbances acting on the system to be controlled and the latter a set of reference signals. In what follows we assume that the exogenous signal is generated by a linear system, denoted exosystem, described by the equation

$$\sigma d = Sd, \tag{2}$$

with S a matrix with constant entries. Note that, under this assumption, it is possible to generate, for example, constant or polynomial references/disturbances and sinusoidal references/disturbances with any given frequency.

The variable $e(t)$, denoted tracking error, is a measure of the error between the ideal behavior of the system and the actual behavior. Ideally, the variable $e(t)$ should be regulated to zero, i.e., should converge asymptotically to zero, despite the presence of the disturbances. If this happens, we say that the tracking error is regulated to zero, i.e., converges asymptotically to zero; hence, the disturbances are not affecting the asymptotic behavior of the system and the output $Cx(t)$ is asymptotically tracking the reference signal $-Qd(t)$. In general the tracking error does not naturally converge to zero; hence, it is necessary to determine an input signal $u(t)$ which *drives* it to zero. The simplest possible way to construct such an input signal is to assume that it is generated via static feedback of the state $x(t)$ of the system to be controlled and of the state $d(t)$ of the exosystem, i.e.,

$$u = Kx + Ld. \tag{3}$$

In practice it is unrealistic to assume that both $x(t)$ and $d(t)$ are measurable; hence, it may be more natural to assume that the input signal $u(t)$ is generated via dynamic feedback of the error signal only, i.e., it is generated by the system

$$\sigma\chi = F\chi + Ge$$
$$u = H\chi, \tag{4}$$

with $\chi(t) \in \mathbb{R}^\nu$, for some $\nu > 0$, and F, G, and H matrices with constant entries.

Using the above definitions, it is possible to formally pose the regulator problem as follows.

Definition 1 (Full information regulator problem) Consider the system (1), driven by the exosystem (2) and interconnected with the controller (3). The full information regulator problem is the problem of determining the matrices K

and L of the controller such that ((S) stands for stability and (R) for regulation):

(S) The system $\sigma x = (A + BK)x$ is asymptotically stable.

(R) All trajectories of the system

$$
\begin{aligned}
\sigma d &= Sd, \\
\sigma x &= (A + BK)x + (BL + P)d, \quad (5) \\
e &= Cx + Qd,
\end{aligned}
$$

are such that $\lim_{t \to \infty} e(t) = 0$.

Definition 2 (Error feedback regulator problem) Consider the system (1), driven by the exosystem (2) and interconnected with the controller (4). The error feedback regulator problem is the problem of determining the matrices F, G, and H of the controller such that:

(S) The system

$$
\begin{aligned}
\sigma x &= Ax + BH\chi, \\
\sigma \chi &= F\chi + GCx,
\end{aligned}
$$

is asymptotically stable.

(R) All trajectories of the system

$$
\begin{aligned}
\sigma d &= Sd, \\
\sigma x &= Ax + BH\chi + Pd, \\
\sigma \chi &= F\chi + G(Cx + Qd), \\
e &= Cx + Qd,
\end{aligned} \quad (6)
$$

are such that $\lim_{t \to \infty} e(t) = 0$.

The Full Information Regulator Problem

Consider the full information regulator problem and assume the following.

Assumption 1 The matrix S of the exosystem has all eigenvalues with nonnegative real part, in the case of continuous-time systems, or with modulo not smaller than one, in the case of discrete-time systems.

Assumption 2 The system (1) with $d = 0$ is reachable.

Assumption 1 implies that there are no initial conditions $d(0)$ such that the signal $d(t)$ converges (asymptotically) to zero. This assumption is not restrictive. In fact, disturbances converging to zero do not have any effect on the asymptotic behavior of the system, and references which converge to zero can be tracked simply by driving the state of the system to zero, i.e., by stabilizing the system. Assumption 2 implies that it is possible to arbitrarily assign the eigenvalues of the matrix $A + BK$ by a proper selection of K. Note that, in practice, this assumption can be replaced by the weaker assumption that the system (1) with $d = 0$ is stabilizable.

We now present a preliminary result which is instrumental to derive a solution to the full information regulator problem.

Lemma 1 *Consider the full information regulator problem. Suppose Assumption 1 holds. Suppose, in addition, that there exist matrices K and L such that condition (S) holds.*

Then condition (R) holds if and only if there exists a matrix $\Pi \in \mathbb{R}^{n \times r}$ such that the equations

$$
\begin{aligned}
\Pi S &= (A + BK)\Pi + (P + BL), \\
0 &= C\Pi + Q,
\end{aligned} \quad (7)
$$

hold.

Proof Consider the system (5) and the coordinates transformation

$$
\begin{aligned}
\hat{d} &= d, \\
\hat{x} &= x - \Pi d,
\end{aligned}
$$

where Π is the solution of the equation

$$
\Pi S = (A + BK)\Pi + (P + BL).
$$

This equation is a so-called Sylvester equation. The Sylvester equation is a (matrix) equation of the form

$$
A_1 X = XA_2 + A_3,
$$

in the unknown X. This equation has a unique solution, for any A_3, if and only if the matrices A_1 and A_2 do not have common eigenvalues. Note that, by condition (S) and Assumption 1, there is a unique matrix Π which solves this equation. In the new coordinates $\hat{x}$ and $\hat{d}$, the system is described by the equations

$$\sigma \hat{d} = S\hat{d},$$
$$\sigma \hat{x} = (A + BK)\hat{x},$$
$$e = C\hat{x} + (C\Pi + Q)\hat{d}.$$

By condition (S) $\lim_{t \to \infty} \hat{x}(t) = 0$, hence condition (R) holds, by Assumption 1, if and only if $C\Pi + Q = 0$. In summary, under the stated assumptions, condition (R) holds if and only if there exists a matrix Π such that Eqs. (7) hold.

We are now ready to state and prove the result which provides conditions for the solvability of the full information regulator problem.

Theorem 1 *Consider the full information regulator problem. Suppose Assumptions 1 and 2 hold. There exists a full information control law described by Eq. (3) which solves the full information regulator problem if and only if there exist two matrices Π and Γ such that the equations*

$$\Pi S = A\Pi + B\Gamma + P,$$
$$0 = C\Pi + Q, \tag{8}$$

hold.

Proof (Necessity) Suppose there exist two matrices K and L such that conditions (S) and (R) of the full information regulator problem hold. Then, by Lemma 1, there exists a matrix Π such that Eqs. (7) hold. As a result, the matrices Π and $\Gamma = K\Pi + L$ are such that Eqs. (8) hold.

(Sufficiency) The proof of the sufficiency is constructive. Suppose there are two matrices Π and Γ such that Eqs. (8) hold. The full information regulator problem is solved selecting K and L as follows. The matrix K is any matrix such that the system $\sigma x = (A + BK)x$ is asymptotically stable. By Assumption 2,

such a matrix K does exist. The matrix L is selected as $L = \Gamma - K\Pi$. This selection is such that condition (S) of the full information regulator problem holds; hence, to complete the proof, we have only to show that, with K and L as selected above, Eqs. (7) hold. This is trivially the case. In fact, replacing L in (7) yields Eqs. (8), which hold by assumption. As a result, also condition (R) of the full information regulator problem holds, and this completes the proof.

The proof of Theorem 1 implies that a controller which solves the full information regulator problem is described by the equation

$$u = Kx + (\Gamma - K\Pi)d,$$

with K such that a stability condition holds, and Π and Γ such that Eqs. (8) hold. By Assumption 2, the stability condition can be always satisfied. As a result, the solution of the full information regulator problem relies upon the existence of a solution of Eqs. (8).

The FBI Equations

Equations (8), known as the Francis-Byrnes-Isidori (FBI) equations, are linear equations in the unknowns Π and Γ, for which the following statement holds.

Lemma 2 *Equations (8), in the unknowns Π and Γ, are solvable for any P and Q if and only if*

$$\text{rank} \begin{bmatrix} sI - A & B \\ C & 0 \end{bmatrix} = n + p, \tag{9}$$

for all s which are eigenvalues of the matrix S.

For single-input, single-output systems (i.e., $m = p = 1$), the condition expressed by Lemma 2 has a very simple interpretation. In fact, the complex numbers s such that

$$\text{rank} \begin{bmatrix} sI - A & B \\ C & 0 \end{bmatrix} < n + 1$$

are the zeros of the system

$$\sigma x = Ax + Bu,$$
$$y = Cx,$$

that is the roots of the numerator polynomial of the transfer function $W(s) = C(sI - A)^{-1}B$, i.e., the zeros of $W(s)$. This implies that, for single-input, single-output systems, the full information regulator problem is solvable if and only if the eigenvalues of the exosystem are not zeros of the transfer function of the system (1) with input u, output e, and $d = 0$.

The Error Feedback Regulator Problem

To provide a solution to the error feedback regulator problem, we need to introduce a new assumption.

Assumption 3 The system

$$\begin{bmatrix} \sigma x \\ \sigma d \end{bmatrix} = \begin{bmatrix} A & P \\ 0 & S \end{bmatrix} \begin{bmatrix} x \\ d \end{bmatrix},$$
$$e = \begin{bmatrix} C & Q \end{bmatrix} \begin{bmatrix} x \\ d \end{bmatrix} \tag{10}$$

is observable.

Note that Assumption 3 implies observability of the system

$$\sigma x = Ax,$$
$$y = Cx. \tag{11}$$

To show this property, note that observability of the system (10) implies that

$$\text{rank} \begin{bmatrix} C & Q \\ CA & \vdots \\ \vdots & \vdots \\ CA^{n+r-1} & \vdots \end{bmatrix} = n + r.$$

This, in turn, implies

$$\text{rank} \begin{bmatrix} C \\ CA \\ \vdots \\ CA^{n+r-1} \end{bmatrix} = n$$

and, by Cayley-Hamilton Theorem,

$$\text{rank} \begin{bmatrix} C \\ CA \\ \vdots \\ CA^{n-1} \end{bmatrix} = n,$$

which implies observability of system (11). Similarly to what discussed in the case of Assumption 2, Assumption 3 can be replaced by the weaker assumption that the system (10) is detectable. We are now ready to state and prove the result which provides conditions for the solvability of the error feedback regulator problem.

Theorem 2 *Consider the error feedback regulator problem. Suppose Assumptions 1–3 hold. There exists an error feedback control law described by Eq. (4) which solves the full information regulator problem if and only if there exist two matrices Π and Γ such that the equations*

$$\Pi S = A\Pi + B\Gamma + P,$$
$$0 = C\Pi + Q, \tag{12}$$

hold.

Remark Theorem 2 can be alternatively stated as follows. Consider the error feedback regulator problem. Suppose Assumptions 1–3 hold. Then the error feedback regulator problem is solvable if and only if the full information regulator problem is solvable.

Proof (Necessity) The proof of the necessity is similar to the proof of the necessity of Theorem 1, hence omitted.

(Sufficiency) The proof of the sufficiency is constructive. Suppose there are two matrices Π and Γ such that Eqs. (12) hold. Then, by Theorem 1, the full information control law $u = Kx + (\Gamma - K\Pi)d$, with K such that the system $\sigma x = (A + BK)x$ is asymptotically stable,

solves the full information regulator problem. This control law is not implementable, because we only measure e. However, by Assumption 3, it is possible to build asymptotic estimates ξ and δ of x and d; hence, implement the control law

$$u = K\xi + (\Gamma - K\Pi)\delta. \tag{13}$$

To this end, consider an observer described by the equation

$$\begin{bmatrix} \sigma\xi \\ \sigma\delta \end{bmatrix} = \begin{bmatrix} A & P \\ 0 & S \end{bmatrix} \begin{bmatrix} \xi \\ \delta \end{bmatrix}$$
$$+ \begin{bmatrix} G_1 \\ G_2 \end{bmatrix} \left(\begin{bmatrix} C & Q \end{bmatrix} \begin{bmatrix} \xi \\ \delta \end{bmatrix} - e \right)$$
$$+ \begin{bmatrix} B \\ 0 \end{bmatrix} \begin{bmatrix} K & \Gamma - K\Pi \end{bmatrix} \begin{bmatrix} \xi \\ \delta \end{bmatrix}.$$

The estimation errors $e_x = x - \xi$ and $e_d = d - \delta$ are such that

$$\begin{bmatrix} \sigma e_x \\ \sigma e_d \end{bmatrix} = \left(\begin{bmatrix} A & P \\ 0 & S \end{bmatrix} + \begin{bmatrix} G_1 \\ G_2 \end{bmatrix} \begin{bmatrix} C & Q \end{bmatrix} \right)$$
$$\begin{bmatrix} e_x \\ e_d \end{bmatrix}; \tag{14}$$

hence, by Assumption 3, there exist G_1 and G_2 that assign the eigenvalues of this error system. Note now that the control law (13) can be rewritten as $u = Kx + (\Gamma - K\Pi)d - (Ke_x + (\Gamma - K\Pi)e_d)$; hence, the control law is composed of the full information control law, which solves the regulator problem, and of an additive disturbance, which decays exponentially to zero. Such a disturbance does not affect the regulation requirement, provided the closed-loop system is asymptotically stable. Therefore, to complete the proof, we need to show that condition (S) holds. In the coordinates x, e_x, and e_d, the closed-loop system, with $d = 0$, is described by the equations

$$\begin{bmatrix} \sigma x \\ \sigma e_x \\ \sigma e_d \end{bmatrix} = \begin{bmatrix} A + BK & -BK & -B(\Gamma - K\Pi) \\ 0 & A + G_1C & P + G_1Q \\ 0 & G_2C & S + G_2Q \end{bmatrix}$$
$$\begin{bmatrix} x \\ e_x \\ e_d \end{bmatrix}. \tag{15}$$

Recall that the matrices G_1 and G_2 have been selected to render system (14) asymptotically stable and that K is such that the system $\sigma x = (A + BK)x$ is asymptotically stable. As a result, system (15) is asymptotically stable.

The Internal Model Principle

The proof of Theorem 2 implies that a controller which solves the error feedback regulator problem is described by equations of the form (4) with

$$\chi = \begin{bmatrix} \xi \\ \delta \end{bmatrix},$$

$$F = \begin{bmatrix} A + G_1C + BK & P + G_1Q + B(\Gamma - K\Pi) \\ G_2C & S + G_2Q \end{bmatrix}, \tag{16}$$

$$G = \begin{bmatrix} G_1 \\ G_2 \end{bmatrix}, \qquad H = \begin{bmatrix} K & \Gamma - K\Pi \end{bmatrix},$$

K, G_1, and G_2 such that a stability condition holds and Π and Γ such that Eqs. (12) hold. This controller, and in particular the matrix F, possesses a very interesting property.

Proposition 1 (Internal model property) *The matrix F in Eq. (16) is such that*

$$F\Sigma = \Sigma S,$$

for some matrix Σ of rank r. In particular, any eigenvalue of S is also an eigenvalue of F.

Proof Let

$$\Sigma = \begin{bmatrix} \Pi \\ I \end{bmatrix}$$

and note that $\text{rank}\,\Sigma = r$, by construction, and that

$$F\Sigma = \begin{bmatrix} A\Pi + G_1 C\Pi + BK\Pi + P + G_1 Q \\ + B(\Gamma - K\Pi) - G_2 C\Pi + S - G_2 Q \end{bmatrix}$$

$$= \begin{bmatrix} (A\Pi + B\Gamma + P) + G_1(C\Pi + Q) \\ S - G_2(C\Pi + Q) \end{bmatrix}$$

$$= \begin{bmatrix} \Pi S \\ S \end{bmatrix} = \Sigma S,$$

hence the first claim. To prove the second claim, let λ be an eigenvalue of S and v the corresponding eigenvector. Then $Sv = \lambda v$; hence,

$$F\Sigma v = \Sigma Sv = \lambda \Sigma v,$$

which shows that λ is an eigenvalue of F with eigenvector Σv, and this proves the second claim.

It is possible to prove that the property highlighted in Proposition 1 is shared by all error feedback control laws which solve the considered regulation problem. This property, which is often referred to as the internal model principle, can be interpreted as follows. The control law solving the regulator problem has to *contain* a copy of the exosystem, i.e., it has to be able to generate, when $e = 0$, a copy of the exogenous signal.

Summary and Future Directions

The problem of tracking and regulation for linear systems in the presence of references and/or disturbances generated by a linear signal generator has been solved. It has been shown that the problem is solvable provided a system of linear matrix equations admits a solution. The tracking and regulation problem can be studied and solved for more general classes of systems, including nonlinear systems, distributed parameter systems, and hybrid systems, exploiting the same ideas presented in this article.

Tracking Model Predictive Control

Daniel Limon and Teodoro Alamo
Departamento de Ingeniería de Sistemas y Automática, Escuela Superior de Ingeniería, Universidad de Sevilla, Sevilla, Spain

Abstract

The main objective of tracking model predictive control is to steer the tracking error, that is, the difference between the reference and the output, to zero while the constraints are satisfied. In order to predict the expected evolution of the tracking error, some assumptions on the future values of the reference must be considered. Since the reference may differ from expected, the tracking problem is inherently uncertain.

The most extended case is to assume that the reference will remain constant along the prediction horizon. Tracking predictive schemes for constant references are typically based on a two-layer control structure in which, provided the value of the reference, first, an appropriate set point is computed and then a nominal MPC

T

is designed to steer the system to this target. Under certain assumptions, closed-loop stability can be guaranteed if the initial state is inside the feasibility region of the MPC. However, if the value of the reference is changed, then there is no guarantee that feasibility and stability properties of the resulting control law hold. Specialized predictive controllers have been designed to deal with this problem. Particularly interesting is the so-called MPC for tracking, which ensures recursive feasibility and asymptotic stability of the set point when the value of the reference is changed.

The presence of exogenous disturbances or model mismatches may lead to the controlled system to exhibit offset error. Offset-free control in the presence of unmeasured disturbances can be addressed by using disturbance models and disturbance estimators together with the tracking predictive controller.

Keywords

Loss of feasibility; MPC for tracking; Offset-free control; Set-point tracking

Introduction

The problem of designing and stabilizing model predictive control (MPC) schemes to regulate a system to the origin has been widely studied, and there are well-known solutions for varied cases including linear, nonlinear, and uncertain systems, among others (Rawlings and Mayne 2009).

The objective of tracking MPC is to ensure a tracking error, which is the difference between a reference or desired output r and the actual output y, tends to zero.

The most common tracking problem is when the reference r is constant. In this case, the controller is required to steer the state x of the plant and the control input u applied to the plant to a set point (x_r, u_r) where the tracking error y_r is zero and the plant is in equilibrium (at rest); the state x_r is called a target. It is also necessary to ensure that x_r is asymptotically stable for the controlled

system, i.e., that the state x converges to x_r and that, near x_r, small changes in x cause small changes in the subsequent trajectory. A relatively straightforward solution for this problem exists.

Set-point tracking is a relevant control problem in the process industry in which the plant is typically designed to operate at an equilibrium point that maximizes the profit of the plant. In this case, the optimal set point is calculated online by a real-time optimizer (RTO) according to an economic criteria. The set points remain constant for a long period of time, until the RTO, which is executed at a very low frequency, calculates a different set point. The steady-state target associated to the given set point must be calculated and provided to the MPC to track this target.

The tracking problem is considerably more difficult when the reference r varies in a way not known a priori because MPC is naturally suited to deterministic control problems. Uncertainty requires the "invention" of special techniques so that a variety of solutions have been proposed in the literature to deal with a varying reference (Bemporad et al. 1997; Chisci and Zappa 2003; Limon et al. 2008; Maeder and Morari 2010; Pannocchia and Rawlings 2003; Rossiter et al. 1996).

Another tracking problem arises when there exists a mismatch between the model used for prediction in the optimal control problem and the real plant. If the reference is constant and the model mismatch is sufficiently small not to cause loss of asymptotic stability, the state and control will converge to values at which the predicted tracking error, but not the actual tracking error, is zero. The difference between the predicted and actual values of the output y is known as the offset; offset-free tracking when the reference is constant may be achieved by incorporation of a suitable observer to estimate the offset.

Notation

The set $\mathbb{I}_M$ denotes the set of integers $\{0, 1, \cdots, M\}$. I_n denotes the identity matrix in $\mathbb{R}^{n \times n}$. $\mathbf{z}$ denotes a signal (or time sequence) $\mathbf{z} = \{z(0), z(1), \cdots\}$, whose cardinality is inferred from the context. A signal that depends on a parameter θ is denoted as $\mathbf{z}(\theta)$ and $z(i; \theta)$

denotes its ith element. A closed polyhedron $\mathcal{X} \subset \mathbb{R}^n$ is a set that results of the intersection of a finite number of hyperplanes as follows: $\mathcal{X} = \bigcap_i \{x : F_i x \leq f_i\}$, where $F_i \in \mathbb{R}^{1 \times n}$ and $f_i \in \mathbb{R}$.

Problem Statement

In this article, for the sake of simplicity, we consider that the system to be controlled can be modeled as a linear time-invariant system described by a discrete-time state-space linear model:

$$x(k + 1) = Ax(k) + Bu(k) \qquad (1a)$$

$$y(k) = Cx(k) \qquad (1b)$$

where $x(k) \in \mathbb{R}^n$, $u(k) \in \mathbb{R}^m$, and $y(k) \in \mathbb{R}^p$ are the state, the manipulable inputs, and the outputs of the system at time step k, respectively. This model will be used to calculate the predictions in the predictive controller.

The evolution of the plant must be such that the constraint

$$(x(k), u(k)) \in \mathcal{Z} \qquad (2)$$

is satisfied for all $k \geq 0$. The set $\mathcal{Z}$ is a closed polyhedron. Without loss of generality, we assume that $(0, 0) \in \mathcal{Z}$.

The main objective of tracking model predictive control is to steer the system output to the reference, that is, steer the tracking error $y - r$ to zero, while the constraints are satisfied. In order to predict the expected evolution of the tracking error, some assumptions on the future values of the reference must be considered. Since the reference may differ from expected, the tracking problem is inherently uncertain.

Thus, assuming that the reference signal is known a priori, $\mathbf{r} = \{r(0), r(1), \cdots\}$, the tracking model predictive control law $\kappa(x(k), \mathbf{r})$ must be designed to ensure that the resulting controlled system

$$x(k + 1) = Ax(k) + B\kappa(x(k), \mathbf{r})$$

$$y(k) = Cx(k)$$

satisfies the constraints, i.e., $(x(k), u(k)) \in \mathcal{Z}$ for all $k \geq 0$ is stable and, if it is possible, the controlled output converges to the reference, that is,

$$\lim_{k \to \infty} \|y(k) - r(k)\| = 0.$$

It is assumed that the system is stabilizable and that the outputs are linearly independent. It is also considered that the state is measured and available at each sample.

Tracking MPC for a Constant Reference

The most simple tracking problem is to consider that the reference signal is a constant signal in the future equal to the actual value of the reference, i.e., $r(k) = r$. This control problem is very common in the process industry, for instance, where processes are typically designed to operate at certain equilibrium point.

Determining the Set Point

Corresponding to each value r of the reference is a set point (x_r, u_r) that is ideally an equilibrium point of the prediction model, i.e., it satisfies

$$x_r = Ax_r + Bu_r. \qquad (3)$$

The set point (x_r, u_r) is also required to satisfy

$$y_r = Cx_r = r \qquad (4)$$

and

$$(x_r, u_r) \in \mathcal{Z}$$

so that the tracking error $y - r$ is zero and the constraint (2) is satisfied at the set point. Because the set point is an equilibrium point, the tracking error remains zero once the set point is reached.

Conditions for the existence of a set point possessing the above properties are given in Rawlings and Mayne (2009, Lemma 1.14).

In practice, the condition $(x_r, u_r) \in \mathcal{Z}$ is replaced by $(x_r, u_r) \in \mathcal{Z}_s \subset \text{interior}\{\mathcal{Z}\}$ in

order to ensure that the constraint $(x_r, u_r) \in \mathcal{Z}$ is not active at the set point, and the tracking error requirement is slightly relaxed so that the set point is determined by solving

$$(x_r, u_r) = \arg \min_{(x_s, u_s) \in \mathcal{Z}_s} \ell_t(x_s, u_s, r) \quad (5)$$

where ℓ_t is a convex function, typically a quadratic function as follows:

$$\ell_t(x_s, u_s, r) = \|Cx_s - r\|_{Q_s}^2 + \|u_s\|_{R_s}^2$$

This problem is referred to as steady-state target optimization problem (Rao and Rawlings 1999).

Model Predictive Controller Design

If the reference to be tracked is a constant, i.e., $r(k) = r$ for all k, then the control objective is to stabilize the system and steer the initial state $x(0)$ to the set-point state x_r. As is usual in model predictive control, a finite horizon optimization problem that depends on the current state x and the constant reference r is solved yielding a control sequence $\mathbf{u}^o(x, r) = \{u^o(0; x, r), u^o(1; x, r), \cdots, u^o(N-1; x, r)\}$ and the associated state trajectory $\mathbf{x}^o(x, r) = \{x^o(0; x, r) = x, x^o(1; x, r), \cdots, x^o(N; x, r)\}$, where N is the prediction horizon. The first element of this sequence, namely, $u^o(0; x, r)$, is applied to the system.

Because the reference is constant, the appropriate optimal control problem $P_N(x, r)$ is a slight variation of that discussed in the article ▶ Nominal Model-Predictive Control and is defined by

$$\min_{\mathbf{u}} \sum_{j=0}^{N-1} \ell(x(j), u(j), r) + V_f(x(N), r)$$

$$s.t. \ x(0) = x, \quad (6a)$$

$$x(j+1) = Ax(j) + Bu(j),$$
$$j \in \mathbb{I}_{N-1} \quad (6b)$$

$$(x(j), u(j)) \in \mathcal{Z}, \quad j \in \mathbb{I}_{N-1} \quad (6c)$$

$$x(N) \in X_f(r) \quad (6d)$$

The stage cost function $\ell(\cdot)$ is a measure of the predicted tracking error set point, that is, $\ell(x_r, u_r, r) = 0$ and $\ell(x, u, r) \geq \alpha_1(\|x - x_r\|)$. The terminal cost function $V_f(\cdot)$ is such that

$$\alpha_2(\|x - x_r\|) \leq V_f(x_r, r) \leq \alpha_3(\|x - x_r\|).$$

Functions α_i are $\mathcal{K}_\infty$ functions (see the article ▶ Nominal Model-Predictive Control). The set of states where this optimization problem is feasible is denoted as $X_N(r)$.

The solution of the optimal control problem $P_N(x, r)$ yields the receding horizon control law

$$\kappa_N(x, r) = u^o(0; x, r)$$

and the system under model predictive control satisfies

$$x(k+1) = Ax(k) + B\kappa_N(x(k), r) \quad (7)$$

Because the horizon N is finite, x_r is not necessarily asymptotically stable for this system, but asymptotic stability can be ensured if the terminal cost function $V_f(\cdot)$ and the terminal region $X_f(r)$ are chosen appropriately.

The functions $\ell(\cdot)$, $V_f(\cdot)$ and the set $X_f(r)$ must satisfy the following condition.

Stability conditions for nominal MPC: For all $x \in X_f(r)$, there exists a control input u such that $(x, u) \in \mathcal{Z}$ and the successor state $x^+ = Ax + Bu$ are contained in $X_f(r)$ and

$$V_f(x^+, r) - V_f(x, r) \leq -\ell(x, u, r).$$

These conditions are trivially satisfied taking $X_f(r) = x_r$ and $V_f(x, r) = 0$.

Under these assumptions, the optimization problem is recursively feasible, i.e., if $P_N(x(0), r)$ is feasible, then all subsequent problems $P_N(x(i), r)$ are also feasible. Besides, the optimal cost function is a Lyapunov function of the system (7). Then, the set point (x_r, u_r) is an asymptotically stable equilibrium point of the system (7) and the domain of attraction is $X_N(r)$.

Tracking MPC for a Changing Reference

The previous predictive controller is inherently deterministic, since it is assumed that the reference is known and this will remain constant in the future. However, in a realistic scenario, the reference may be changed without a predefined deterministic law or even randomly. In this section, a tracking predictive controller, for the case when the reference is constant or varying but ultimately constant, is presented.

Feasibility and Stability Issues

If the reference r is constant, tracking MPC ensures asymptotic stability of the target state x_r and convergence to zero of the tracking error $y - r$. However, if the reference r varies, recursive feasibility (i.e., feasibility of $P_N(x(k), r(k))$ at each time instant k) and asymptotic stability may be compromised. For each value of r, the feasibility region $X_N(r)$ is the set of states for which $P_N(x, r)$ has a solution; it is also the domain of attraction for the closed-loop system (7). If r changes value from r_1 to r_2, the terminal constraint set $X_f(r_2)$ and the terminal cost function $V_f(\cdot, r_2)$ have to be computed. The current state

x, which lies in $X_N(r_1)$, does not necessarily lie in $X_N(r_2)$ so that $\kappa_N(\cdot, r_2)$ is undefined and the model predictive controller fails.

This phenomenon is illustrated for the double integrator system where

$$A = \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix}, \ B = \begin{bmatrix} 0 & 0.5 \\ 1 & 0.5 \end{bmatrix}, \ C = \begin{bmatrix} 1 & 0 \end{bmatrix}$$

and the set of constraints is given by

$$\mathcal{Z} = \{(x, u) : \|x\|_\infty \leq 5, \ \|u\|_\infty \leq 0.3\}$$

The initial state is $x(0) = (2.91, -1.83)$ and the initial value of the reference is $r_1 = -2$. The corresponding set point is (x_{r_1}, u_{r_1}) where $x_{r_1} = (-2, 0)$ and $u_{r_1} = (0, 0)$. If the reference changes from r_1 to r_2, the new set point is (x_{r_2}, u_{r_2}) where $x_{r_2} = (4.5, 0)$ and $u_{r_2} = (0, 0)$. The horizon is chosen to be $N = 3$ and the domains of attraction for the two values of r are, respectively, $X_3(r_1)$ and $X_3(r_2)$. These two domains, $X_3(r_1)$ and $X_3(r_2)$, are disjoint. While $r = r_1$, the state trajectory commencing at $x(0) \in X_3(r_1)$ remains in $X_3(r_1)$. If r subsequently changes its value to r_2 at time t_1, the model predictive controller

Tracking Model Predictive Control, Fig. 1 Example of the double integrator: terminal regions ($X_f(r_1)$ and $X_f(r_2)$) and domains of attraction of MPC ($X_3(r_1)$, $X_3(r_2)$, and $X_{10}(r_2)$)
fails since $x(t_1)$ does not lie in $X_3(r_2)$. This is illustrated in Fig. 1.

These feasibility and stability issues can be overcome if the predictive controller is redesigned for the new set point. This would require the calculation of a new terminal set and a prediction horizon each time the set point changes. For instance, in the example of Fig. 1, if the terminal constraint is recalculated for r_2 and the prediction horizon is chosen as $N = 10$, then the MPC controller steers the system to the reference r_2 since $x(0) \in X_{10}(r_2)$. This recalculation can be done off-line if the set-point changes are a priori known (Findeisen et al. 2000; Wan and Kothare 2003). Other methods to avoid this issue are designing a predictive controller to provide a certain degree of robustness to set-point variations (Pannocchia 2004; Pannocchia and Kerrigan 2005) and a predictive control law with a mode to recover recursive feasibility (Chisci and Zappa 2003; Rossiter et al. 1996) or using specialized predictive control laws (Magni and Scattolini 2005; Magni et al. 2001). Another solution to this case is to use a reference governor and a predictive controller (Bemporad et al. 1997; Olaru and Dumur 2005).

Stabilizing MPC for Tracking

The idea behind the reference governor is to introduce an artificial reference r^a that is manipulated to ensure that the current state is in the domain of attraction $X_N(r^a)$ while tends to the actual reference r if r remains constant or tends to a constant. In Limon et al. (2008), this idea is used to formulate the MPC for tracking. The artificial reference r^a is an extra decision variable in the optimal control problem to avoid the loss of feasibility issue. In order to enforce the convergence to the actual reference r, a term that penalizes the deviation between the artificial reference r^a and the actual reference r, $\ell_o(r^a, r)$ is added. This function is assumed to be convex in r^a. A suitable choice of this term is the cost function of the steady-state target calculator (5), i.e., $\ell_o(r^a, r) = \ell_t(x_{r^a}, u_{r^a}, r)$, where (x_{r^a}, u_{r^a}) is the artificial set point associated to the artificial reference r^a.

The optimal model predictive control problem $P_N^t(x, r)$ for tracking is given by

$$\min_{\mathbf{u}, r^a} \sum_{j=0}^{N-1} \ell(x(j), u(j), r^a) + V_f(x(N), r^a)$$
$$+ \ell_o(r^a, r) s.t. x(0) = x, \tag{8a}$$

$$x(j + 1) = Ax(j) + Bu(j),$$
$$j \in \mathbb{I}_{N-1} \tag{8b}$$

$$(x(j), u(j)) \in \mathcal{Z}, \quad j \in \mathbb{I}_{N-1} \tag{8c}$$

$$r^a \in \mathcal{R} \tag{8d}$$

$$(x(N), r^a) \in \Gamma \tag{8e}$$

where $\mathcal{R} = \{r : (x_r, u_r) \in \mathcal{Z}_s, Ax_r + Bu_r = x_r, Cx_r = r\}$.

Condition (3) is an extended terminal constraint of both the terminal state $x(N)$ and the artificial reference r^a. The feasibility region of this optimization problem X_N^t is the set of states that can be steered to any reference of the set $\mathcal{R}$ in N steps, that is,

$$X_N^t = \bigcup_{r^a \in \mathcal{R}} X_N(r^a)$$

The terminal cost function $V_f(\cdot)$ and the terminal constraint set, Γ, must satisfy appropriately modified stability conditions in order to ensure recursive feasibility and asymptotic stability of (x_r, u_r). The stability conditions are the following.

Stability conditions for tracking MPC: For all $(x, r^a) \in \Gamma$, there exists a u satisfying:
(i) $(x, u) \in \mathcal{Z}$
(ii) the successor state $x^+ = Ax + Bu$ such that $(x^+, r^a) \in \Gamma$ and
$V_f(x^+, r^a) - V_f(x, r^a) \leq -\ell(x, u, r^a)$.

As shown in Limon et al. (2008), if the terminal control law is chosen as $u = K(x - x_{r^a}) + u_{r^a}$ with K such that the eigenvalues of $A + BK$ are in the unitary disk, then the terminal set Γ can be calculated using standard algorithms to compute positively invariant sets for constrained linear

systems and it is a polyhedron. A simple choice of the terminal cost and constraint satisfying these assumptions is $V_f(\cdot) = 0$ and $\Gamma = \{(x, r^a) : x = x_{r^a}\}$.

Theorem 1 *If the stability conditions for tracking MPC hold, then predictive control law derived from the optimal control problem $P_N^t(x, r)$ is such that:*

1. *For all feasible initial state, i.e., $x(0) \in X_N^t$, and for all $r \in \mathbb{R}^p$, the optimization problem is recursively feasible, that is, if $P_N^t(x(0), r)$ is feasible, then all the subsequent problems $P_N^t(x(i), r)$ are also feasible.*
2. *If r is admissible, i.e., $r \in \mathcal{R}$, then the set point (x_r, u_r) is an asymptotically stable equilibrium point of the closed-loop system and the domain of attraction is X_N^t.*
3. *If r is not admissible, that is, $r \notin \mathcal{R}$, then the set point (x_{r*}, u_{r*}) such that*

$$r^* = \arg \min_{r^a \in \mathcal{R}} \ell_o(r^a, r)$$

   is asymptotically stable and the domain of attraction is X_N^t.
4. *The domain of attraction X_N^t is larger than the domain of the nominal MPC for any reference $r \in \mathcal{R}$, that is, $X_N(r) \subseteq X_N^t$, and contains all the equilibrium points contained in $\mathcal{Z}_s$.*
5. *If the reference $r(k)$ is not constant and converges to a steady value r, the optimization problem is recursively feasible and the set point (x_r, u_r) is an asymptotically stable equilibrium point for all $x(0) \in X_N^t$.*

In Fig. 2a the aforementioned properties are illustrated for the example of the double integrator. The MPC for tracking has been designed with the same prediction horizon $N = 3$ and the same terminal control law and the terminal cost function that in the previous tracking MPC case. The initial state is also the same and the reference signal is $r(k) = r_2$ for $k \leq 30$ and $r(k) = r_1$ for $k > 30$. Notice that the tracking MPC cannot be used to do this without redesign. In Fig. 2a, it can be seen that the domain of attraction of the MPC for tracking X_3^t is larger than the domain provided by the standard tracking MPC $X_3(r_1)$ or $X_3(r_2)$.

This figure also shows the state portrait of the closed-loop trajectory. In Fig. 2b the trajectories of the reference signal **r**, the controlled output **y**, and the artificial target output $y_{r^a} = Cx_{r^a}$ are depicted. Notice the role of the artificial target: y_{r^a} differs from the reference in order to guarantee recursive feasibility and finally converges to the reference r to enforce asymptotic stability.

Offset-Free Tracking

In practice there may exist mismatches between the prediction model and the dynamics of the real plant to be controlled, due, for instance, to un-modeled nonlinearities or unmeasured disturbances. This would require to design the predictive controller to be robust to this uncertain effects. Assuming that the predictive controller based on nominal predictions is robustly stable and considering that the controlled system converges to a steady state, there may exist a steady error between set point and the output.

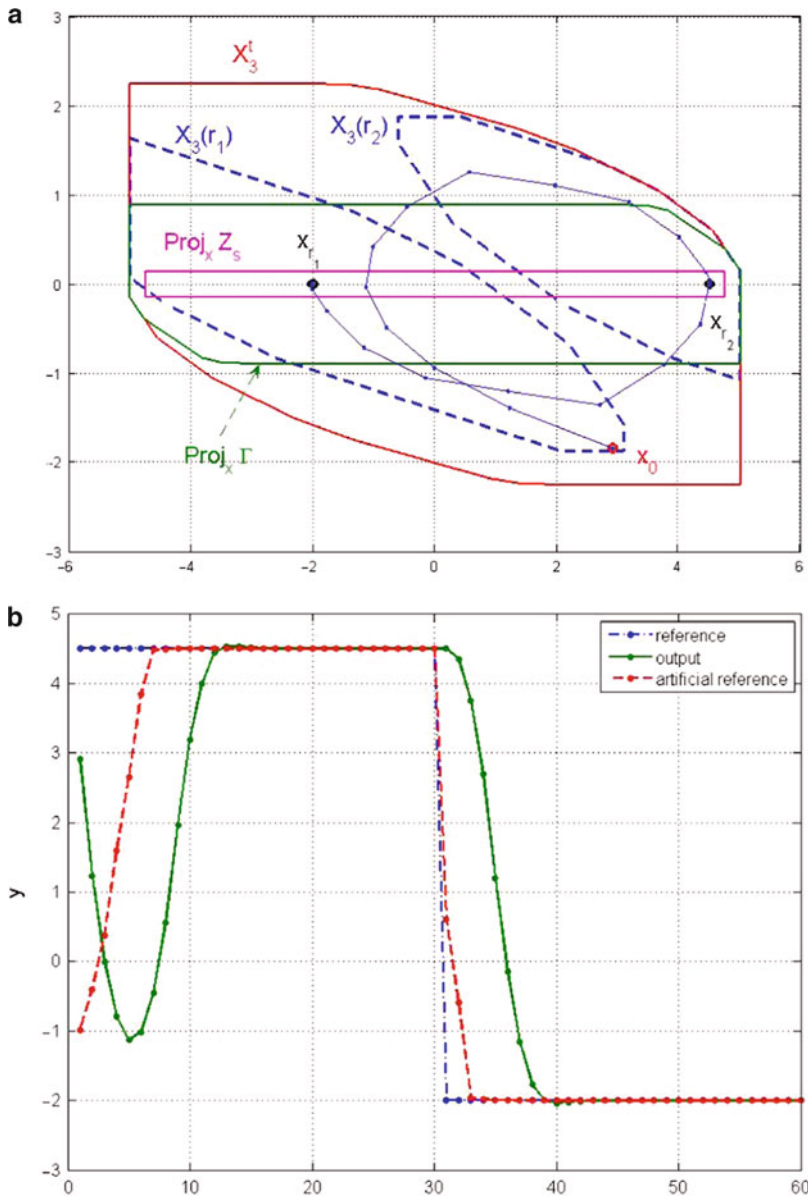
This offset can be canceled taking into account a prediction model corrected by a disturbance model (Pannocchia and Rawlings 2003). To achieve offset-free control, the disturbance is assumed to be an integrating disturbance as follows:

$$x(k + 1) = Ax(k) + Bu(k) + B_d d(k) \quad \text{(9a)}$$

$$d(k + 1) = d(k) \quad \text{(9b)}$$

$$y(k) = Cx(k) + D_d d(k) \quad \text{(9c)}$$

Matrices B_d and D_d define the disturbance model and these are chosen to guarantee offset-free control. They are typically chosen as $B_d = 0$ and $D_d = I_p$.

The disturbance signal $d(k)$ is estimated using an observer based on the disturbance model. The disturbance model and the estimator gains can be calculated separately, but this may lead to a poor closed-loop performance. A joint design procedure has been proposed in Pannocchia and Bemporad (2007).


Tracking Model Predictive Control, Fig. 2 The double integrator controlled by the MPC for tracking. (**a**) Comparison of the domains of attraction of the tracking MPC $X_3(r_1)$ and $X_3(r_2)$ vs. the domain of attraction of the MPC for tracking X_3^t. (**b**) Trajectories of the reference, the controlled output, and the artificial reference r^a

Once the estimated disturbance $\hat{d}$ is available, the corrected prediction model (9) must be used to calculate the MPC target in the steady-state target optimization problem (5) (x_r, u_r) and to calculate the predictions in the optimization problem $P_N(x, x_r, u_r, \hat{d})$.

Future Directions

Tracking model predictive control is an inherently uncertain control problem due to the unexpected changes in the reference. Constant reference tracking has been widely studied and there exist a number of nice solutions.

The case of trajectory tracking is not as mature as the set-point tracking case. If the reference signal is known a priori, this can be used to calculate the predicted cost. This control problem can be solved by using a two-layer structure: a trajectory planning on top of a predictive control law that steers the system to the trajectory target. Asymptotic stability to the trajectory target can be proved using terminal equality constraint resorting on the regulation problem. Another interesting line is to assume that the reference is the output of a certain dynamic system. For different families of trajectories, such as ramps or sinusoidal signals, Maeder and Morari (2010) has proposed a reference tracking MPC based on extended disturbance models.

The problem of tracking MPC in case of unknown (or changing) reference signals can be considered an open problem that deserves more research efforts.

Another interesting control problem is the tracking of unreachable (equilibrium point as well as trajectory) targets. Recently this problem has been posed as an economic model predictive control problem (Rawlings and Mayne 2009). Therefore, the stabilizing design of economic MPC presented in Angeli et al. (2012) can be extended to the case of tracking unreachable targets.

Abstract

Automotive transmissions are fundamental components in modern vehicles. They are required to make the engine operating at the most efficient operating point for providing the necessary torque at the wheels and minimizing the fuel consumptions. Moreover, transmissions should be able to smooth or to filter out power source torque oscillations that can appear in the driveline. For achieving such objectives, the automotive industry has looked at different technological solutions. The introduction of electronically controlled transmissions contributed to augment the possibilities of new solutions that would not have been implementable without the flexibility and the performance of electronic control. Thus, recent technological developments of automotive transmissions gave the opportunity to engineers and control scientists for investigating challenging control problems with daily life practical applications.

Introduction

In motor vehicles, the transmission is an important system that transfers the power generated by the *internal combustion engine* to the wheels, according to the driver's requests. The transmission, together with the engine, the driveshaft, differential, and driven wheels, constitutes the *powertrain* (sometimes *driveline* or *drive train* is used to denote the powertrain excluding the engine and the transmission). The first fundamental objective of a transmission is to adjust the ratio between the wheel speed and the engine speed in order to achieve the optimal operating point of the engine, independently of the vehicle velocity. Indeed, typical internal combustion engines provide low torques at low engine speeds, and, thus, it is necessary to amplify the torque making the engine work at higher speeds when the vehicle is at low speeds, e.g., during a launch from standstill. From an equivalent point of view, the transmission allows to amplify the engine

torque transferred to the wheels when higher accelerations are needed. For such reasons, every type of transmission has some devices that allow selection of select the ratio between its input shaft angular speed (engine side) and its output shaft angular speed (the side toward the wheels). The transmission's input shaft is connected to the *flywheel* of the engine, while the output shaft of the transmission is connected to the *final drive* (containing the *differentials*) through the *drive shaft*. (In British English, the term propeller shaft is also used when dealing with a rear-wheel-driven vehicle.) Even though such subsystems are differently located depending on the vehicle layout (if front-wheel or rear-wheel driven or even all-wheel driven), they all are parts of the powertrain and determine its behavior.

Transmissions can be viewed also as systems that allow the transfer of power from the engine to the vehicle in a smooth and efficient way. In order to achieve such basic and fundamental objectives as well as to improve fuel economy, performance, and drivability, many technologies have been introduced into the market of automotive transmissions.

Types of Transmissions

In **manual transmissions** (MT), a set of gears provides each the different speed conversion ratios, and any gear can be selected by the driver by acting on the shift lever. For interrupting the power flow during the gear selection, a *clutch* is requested that disconnects the transmission from the flywheel of the engine and reconnects it just after the selection of the new gear. All such operations are performed manually by the driver.

Automatic transmissions (AT) are the other well-known type of automotive transmissions. Hydraulic ATs do not have the clutch for connecting the transmission to the flywheel; instead they have a *torque converter* that provides the fluid coupling between the transmission and the engine realizing both a damping of the powertrain vibrations and a torque multiplication. Moreover in ATs, a set of *planetary gear* allows the selection

of different gear ratios. The driver selects only the operation mode, and the selection of the gear is implemented through the electronic control. The main limits of these transmissions are the low efficiency (particularly due to the slip of the torque converter), a larger space requirement, and a higher weight. The new generations of automatic transmissions have reduced such disadvantages, thanks to the use of lightweight materials and more shifting steps, and, above all, the replacement of conventional hydraulic components by electronic and electrohydraulic counterparts.

Indeed the electronic transmission control not only improves fuel economy, performances, and drivability, but it also gives flexibility and new possibilities (e.g., diagnostics, fault detection, integration with other subsystems) that overcome the intrinsic disadvantages like complexity and development cost (Deur et al. 2006). Electronic transmission control played a fundamental role also in the introduction of new technologies that have exploited automatic control techniques. Thus, in recent years, continuously variable transmissions, automated manual transmissions, dual clutch transmissions, and electrically variable transmissions have appeared in the market, which was traditionally dominated by ATs and MTs (Sun and Hebbale 2005).

An **automated manual transmission** (AMT) system can be viewed as an MT with some controlled actuators as add-ons: it still has a (dry or wet) clutch assembly and a multispeed gearbox, both of which are equipped with electromechanical or electrohydraulic actuators which are commanded by an electronic control unit. In AMTs the gearshift can be decided automatically by the transmission control unit (TCU) or even manually by the driver. In both cases after the gearshift command, the TCU manages all the shifting steps, through suitable signals sent to the engine, the clutch assembly, and the gearbox. This technology has the advantages of lower weight, lower costs, and higher efficiency with respect to ATs.

It is worth highlighting one limitation of AMTs, the reduction in driving comfort caused by lack of traction during gear shift actuation.

T

Indeed the torque interruption leads to perceived jerks due to vehicle acceleration discontinuity and is very different compared to the smoother conventional automatic transmissions with torque converters (Lucente et al. 2007).

Automated manual transmissions have become popular in Europe for their higher performances with respect to MTs and for their lower cost compared to ATs. In North America, instead, their use is limited because of the torque interruption during shifts that causes some discomfort.

An offshoot of the AMT is the **dual clutch transmission** (DCT), in which the gearbox assembly has two separate and independent clutches, one for odd gears and one for even gears. In a DCT, shifts can be achieved without noticeable torque gap, by applying the engine torque to one clutch while the engine torque is being disconnected from the other clutch. The result is gentle, jerk-free gear shifts with the same comfortable driving of an automatic transmission combined with the efficiency and the performance of an economic manual transmission. In both DCT and AMT, electronic control (in particular aimed to solve the clutch engagement control problem) is the key to ensuring a smooth torque transfer.

As a further transmission technology, the **continuously variable transmission** (CVT) enables the engine to operate in a wide range of speed and load conditions independently from the speed and the torque requests of the vehicle. A modern CVT system consists of a steel belt that runs between two variable-width pulleys. The distance between pulley cones can be varied to change the gear ratio between shafts, thus generating an infinite number of "gears." A CVT is less efficient than a standard discrete AT due to the losses in the belt-pulley system, but it can improve fuel economy by making the engine work in better operating conditions. Related to CVT is the **electrically variable transmission** (EVT) that appeared in the market with hybrid electric vehicles recently and use electric machines, namely motors/generators with planetary gear sets, so as to enable the function of CVTs with flexibility, controllability, and better performance. This type of transmission is usually found in hybrid electric vehicles.

By looking at the different types of automotive transmissions, it is possible to classify electronically controlled transmissions into two groups: discrete ratio and continuously variable transmissions. The first group deals with the problem of automating the shift scheduling ("when-to") or also controlling the shift execution ("how-to") (Hrovat and Powers 1988). The latter group deals with control problems that live in a continuous domain (like classical "process control"), and that allows the design of simpler control software. Indeed the discrete ratio transmissions are more complex to control since they determine many large transients of short duration due to gear shifts, and moreover their intrinsic mixed discrete-continuous nature gives rise to dynamic systems in which continuous time dynamics interact with discrete event dynamics. In other words such class of controlled transmissions can be considered a significant application of what control theory calls **hybrid systems**. This makes transmission control a very interesting and challenging control engineering problem.

Control Problems for Automotive Transmissions

Electronic control applied to automotive transmissions enables improved efficiency and fuel economy, better shift quality and comfort, and flexible driving. In order to achieve such objectives, different approaches can be used for designing suitable control laws, and a hierarchical approach is often required for dealing with the complexity of the several problems. Thus, recently produced cars together with the engine control unit also have a TCU that manages all transmission operations and sends command signals to actuators in order to perform the desired behavior. Some dedicated devices are then available for tackling challenging control problems and for trying to solve them exploiting classical feedback and/or modern model-based control.

Low Level Control

In electronically controlled transmissions, many hydraulic functions of conventional transmissions have to be replaced by electrohydraulic systems. Thus it is a fundamental requirement to be able to control actuators in a suitable way. Usually classical PID regulators are employed for this type of low level controls whose aim consists of regulating some variables to reference values computed by a higher level controller. For instance, in AMTs the concentric slave cylinder is controlled to make the clutch disk follow a position reference signal computed by the TCU. The clutch position reference can be obtained by taking into account some models of the clutch transmission characteristic (Vasca et al. 2011), thus realizing a feedforward/feedback architecture.

Other examples of low level controls in automotive transmissions are related to the clutch fill process (Song et al. 2010) in ATs, or the line pressure control, or also the CVT belt load control.

Calibration Process

Most of the industrial control strategies applied to automotive transmissions are based on feedforward/feedback architectures. Feedforward control typically relies on detailed models of the transmission that quite often consist of some lookup tables rather than specific physical models. Lookup tables are used also for implementing adaptive feedback controllers, and thus, the use of tables with calibrated variables is widespread in automotive transmission control. With the increasing number of required functionalities, the calibration process for transmission control subsystems becomes more and more complex. Then it becomes important to investigate automated and systematic approaches for the calibration process in order to improve the reliability and performances and, above all, for diminishing the development time.

Of course, a different approach that looks at developing model-based control strategies could be the way to reduce the number of calibration variables and, thus, the calibration effort and time. The main obstacle to that is the uncertain environment that makes it very challenging to find robust control solutions.

Gear Shifting

The gear shift execution is a common problem in all discrete ratio transmission. In Figs. 1 and 2, the schemes of two transmission architectures are reported. Although we are looking at completely different typologies like ATs and AMTs, the gear shift problem is almost the same from an abstract point of view: commanding the actuator for getting a desired torque at the primary shaft of the transmission in order to have the possibility of disengaging the old gear, engaging the neutral gear, and then engaging the new gear, without shuffles, and limiting the jerk experienced by the driver. In ATs the basic idea is to control the hydraulic pressures of the torque converter to transfer smoothly the power from the engine to the driveline while minimizing the torque disturbance at the output shaft. Analogously in AMTs with dry clutch, the actuator is commanded for positioning the clutch disk toward the flywheel, exerting a pressure that is transformed into the transmitted torque.

For instance, a wet clutch of an automatic transmission gives the following transmitted torque (Deur et al. 2006):

$$T = n \, A_p \, p_{\text{app}} \, \mu(\omega, p_{\text{app}}, \theta) \, r_e \, \text{sgn}(\omega)$$

where n is the number of friction surfaces, A_p is the piston area, p_{app} is the hydraulic pressure, μ is the friction coefficient (depending also on the clutch fluid temperature θ), r_e is the equivalent radius of the clutch, and ω is the clutch slip speed, i.e., the difference between the engine speed and the speed of the input shaft of the transmission.

For a dry clutch of an automated manual transmission (Vasca et al. 2011),

$$T = nF_{pp}(x_{to})\mu(\omega, \theta)r_e \, \text{sgn}(\omega)$$

where F_{pp} is the force exerted by the cushion spring depending on the clutch actuator position x_{to} and θ is the clutch disk temperature.

In both cases, the actuator allows regulation of the torque transmitted, respectively, through the
Transmission, Fig. 1 Architecture of an automatic transmission

Transmission, Fig. 2 Architecture of an automated manual transmission

torque converter or the dry clutch under a slipping condition. The main problem is that in modern transmissions, there are no low-cost torque sensors, and thus, due also to model uncertainties and highly variable operating conditions, it is not possible to regulate the transmitted torque through a closed-loop scheme. What is usually done is to control the engine speed and/or the speed of the input shaft of the transmission. Quite often, their difference (the slip speed) is the variable to be controlled.

Many different approaches have been proposed in the literature for solving such control problems that can be formulated as simply as a regulation problem of the slip speed or as a more complex multivariable control problem that considers the engine and clutch torques as control variables and the slip speed and vehicle speed as controlled variables, possibly solving the problem through robust control tools. The

problem can be formulated quite naturally also as an optimal control problem that aims to minimize the engagement time, the driveline oscillations, or the dissipated energy. For example, by defining the time derivative of the clutch torque as one control variable, the transmitted torque becomes a state variable, and the energy dissipated during the engagement phase can be expressed as the cross product of two state variables (Garofalo et al. 2002)

$$E_d = \int_0^{\bar{t}} \omega(s) T(s) \mathrm{d}s,$$

and the clutch engagement can be expressed as an optimal control problem with free final time (the engagement time, $\bar{t}$) and a final state constraint (i.e., $\omega(\bar{t}) = 0$).

Some authors have also proposed a different solution for the gear shifting problem by

acting through the engine control (Pettersson and Nielsen 2000). The idea is to control the gear shifting using directly the engine as the actuator that allows to modulate the transferred torque to the transmission (see Figs. 1 and 2). In particular the engine is controlled so as to get a zero transferred torque in the transmission and then the neutral gear is engaged. In this way, a virtual clutch is realized.

Driveline Modeling

When model-based control is used for automotive transmissions, it is important to have a good model of the driveline that is detailed enough for capturing the main dynamics and, at the same time, sufficiently simple to deal with for designing not so complex controllers. Vehicular drivelines have many elastic parts making mechanical resonances occurring. Handling such resonances is important for driveability but also for reducing mechanical stresses. Thus driveline control is crucial not only during gear shifting but also for a more general powertrain control that could manage wheel-speed oscillations induced by sudden accelerations or following from the road roughness.

Integrated Powertrain Management

Shift scheduling is an additional interesting problem of electronically controlled transmissions. The shift point is usually based on some measurements like the vehicle speed, the maximum acceleration or throttle angle. In this case the control strategy is open-loop and implemented through lookup tables.

As the number of gears increases, the shift schedule gets more complicated. Thus it becomes important to take into account also the actual driving scenario. For example, entering a curve during uphill driving is quite different relative to a downhill driving situation, so it can be very useful getting information on the steering angle, the road grade, vehicle acceleration, etc. More information, together with new degrees of freedom that are available to modern vehicles (e.g., vehicles with electronic throttle control), give the opportunity to realize an integrated powertrain control which coordinates the engine control and the transmission control allowing to manage the gear scheduling and the gear shifting execution in a more flexible way, trying to optimize the fuel consumption and to improve the driveability (Kim et al. 2007).

Diagnostics

In all automotive applications, safety is a fundamental issue that becomes more and more critical when the number of subsystems and their interaction increases, as it happens when introducing electronic control. Thus, diagnosing faults of control systems is a challenging problem, in particular when there is limited information. To this aim, systems and control theory can be very useful for designing observer or fault detection algorithms that could deal with these types of problems.

Summary and Future Directions

In summary transmission control is a fertile application for looking at challenging problems of much interest for both control scientists and engineers, giving the opportunity for investigating topics like optimal control (e.g., for gear shifting and integrated powertrain control), robust control (for driveline modeling and control), estimation (diagnostics), and adaptive and predictive control.

Technological developments could affect the possibilities and the effectiveness of transmission control. Of course new sensing devices can improve the reliability and the precision of the feedback, but they can also open the door to new control architectures. For instance, the phenomenon of inverse magnetostriction that converts material strain into magnetic property changes can be exploited to measure transmitted torque, and some magnetoelastic torque sensors have been investigated by a number of researchers (Klimartin 2003; Pietron et al. 2013). In this way the gear shifting control problem can be attacked by closing the loop on the transmitted torque measurement, avoiding more or less complex torque observers or, at least, improving the control performances.

Analogous considerations can be carried out at the actuation level. For instance, Kim and Choi (2011) have proposed a new clutch actuator with a self-energizing mechanism so as to amplify the normal force applied on the contact surfaces for the engagement. That idea allows the clutch module to consume less energy for actuating the overall system. Smart-material-based actuation devices were also developed by a number of researchers in recent years (Chaudhuri and Wereley 2012), and some specific applications to automotive transmissions are currently under investigation, like magnetorheological fluid dual clutch transmissions that are discussed in Chen et al. (2012).

At the system level, one of the most interesting research directions deals with the communication and coordination among different control subsystems like the engine control, transmission control, and electronic stability control, with the final aim of integrating all such subsystems for integrated powertrain management.

Recommended Reading

Hrovat et al. (2010) give an overview of automotive transmissions in their chapter on powertrain control of the CRC Control Handbook. Of course transmission control is discussed also in classical automotive control books: one of the first well-known books dedicated to automotive control was Kiencke and Nielsen (2005). There a whole chapter on driveline control deals with driveline modeling and gear shifting for clutch-based transmissions. A more recent book on automotive control is Ulsoy et al. (2012) where transmission control for all-wheel drive vehicles is also presented.

In the scientific literature, many papers deal with transmission control: here, in particular, we would like to cite the optimal control approach for ATs by Haj-Fraj and Pfeiffer (2001), a deep discussion on AMT control in Glielmo et al. (2006), and, more recently, papers on DCTs like Kulkarni et al. (2007) and Senatore (2009); in the latter, the author illustrates the wide selection of patents on dual clutch.

Regarding automotive technologies, an overview of automotive sensors can be found in Fleming (2008), while a discussion on smart materials and the integration of mechanics, materials, and electronics (the so-called mechamatronics discipline) are presented by Munhoz et al. (2007).

Uncertainty and Robustness in Dynamic Vision

Mario Sznaier and Octavia Camps
Electrical and Computer Engineering
Department, Northeastern University,
Boston, MA, USA

Abstract

Dynamic vision is a subfield of computer vision dealing explicitly with problems characterized by image features that evolve in time according to some underlying dynamics. Examples include sustained target tracking, activity classification from video sequences, and recovering 3D geometry from 2D video data. This article discusses the central role that systems theory can play in developing a robust dynamic vision framework, ultimately leading to vision-based systems with enhanced autonomy, capable of operating in stochastic, cluttered environments.

Keywords

Event detection; Multiframe tracking; Structure from motion

Background

In this article, we represent linear time invariant (LTI) systems by their associated transfer matrix $G(z)$. The "size" of $G(z)$, which plays a key role in assessing the effects of uncertainty, will be measured using the $\mathcal{H}_\infty$ norm, defined as $\|G\|_\infty \doteq \sup_\omega \overline{\sigma}\left(G(e^{j\omega})\right)$, where $\overline{\sigma}(.)$ denotes maximum singular value. For scalar systems, this reduces to the peak value of the frequency response (i.e., the maximum gain of the system). In the matrix case, this definition takes into account both the worst-case frequency and spatial direction. Background material on the $\mathcal{H}_\infty$ norm, its computation and its significance in the context of robust control theory, is given in Sánchez–Peña and Sznaier (1998). A general coverage of linear systems theory, including alternative representations of linear systems and their associated properties, can be found, for instance, in Rugh (1996).

Multiframe Tracking

A requirement common to most dynamic vision applications is the *ability to track* objects across frames, in order to collect the data required by a subsequent activity analysis step. Current approaches integrate correspondences between individual frames over time, using a combination of some assumed simple target dynamics (e.g., constant velocity) and empirically learned noise distributions (Isard and Blake 1998; North et al. 2000). However, while successful in many scenarios, these approaches are vulnerable to model uncertainty, occlusion, and appearance changes, as illustrated in Fig. 1.
Frame 150   Frame 95

Uncertainty and Robustness in Dynamic Vision, Fig. 1 Unscented particle filter-based tracking in the presence of occlusion

As shown next, the fragility noted above can be avoided by modeling the motion of the target as the output of a dynamical system, to be identified directly from the available data, along with bounds on the identification error. In the sequel, we consider two different cases: (i) the motion of the target is known to belong to a relatively small set of a priori known motion modalities; and (ii) no prior knowledge is available.

The case of known motion models: Consider first the case where a set of models known to span all possible motions of the target is known a priori, as it is often the case with human motion. In this case, the position y_k of a given target can be modeled as $y(z) = \mathcal{F}(z)e(z) + \eta(z)$ where $\mathbf{e}$ and η_k denote a suitable input and measurement noise, respectively, and where $\mathcal{F}$ admits an expansion of the form $\mathcal{F} = \overbrace{\sum_{j=1}^{N_p} p_j \mathcal{F}^j}^{\mathcal{F}_p} + \mathcal{F}_{np}$. Here $\mathcal{F}^j$ represent the (known) motion modalities of the target and $\|\mathcal{F}_{np}\|_\infty \leq K$, e.g., a bound on the maximum admissible approximation error of the expansion $\mathcal{F}_p$ to $\mathcal{F}$ is available. In the reminder of this article, we will further assume that a set membership descriptions $\eta_k \in \mathcal{N}$ is available and, without loss of generality, that $e(z) = 1$ (i.e., motion of the target is modeled as the impulse response of the unknown operator $\mathcal{F}$).

In this context, the next location of the target feature y_k can be predicted by first identifying the relevant dynamics $\mathcal{F}$ and then using it to propagate its past values. In turn, identifying the dynamics entails finding an operator $\mathcal{F}(z) \in \mathcal{S} \doteq \{\mathcal{F}(z): \mathcal{F} = \mathcal{F}_p + \mathcal{F}_{np}\}$ such that $y - \eta = \mathcal{F}$, precisely the class of interpolation problem addressed in Parrilo et al. (1999). As shown there, finding such an operator reduces to solving a linear matrix inequality (LMI) feasibility problem. Once this operator is found, it can be used in conjunction with a particle (or a Kalman) filter to predict the future location of the target. Figure 2 shows the tracking results obtained using this approach. Here, we used a combination of a priori information: (i) 5 % noise level and (ii) $\mathcal{F}_p \in \text{span}[\frac{1}{z-1}, \frac{z}{z-a}, \frac{z}{(z-1)^2}, \frac{z^2}{(z-1)^2}, \frac{z^2-\cos\omega z}{z^2-2\cos\omega z+1}, \frac{\sin\omega z^2}{z^2-2\cos\omega z+1}]$ where $a \in \{0.9, 1, 1.2, 1.3, 2\}$ and $\omega \in \{0.2, 0.45\}$. The experimental information consisted of the position of the target in $N = 20$ frames, where it was not occluded. Note that, by exploiting predictive power of the identified model, the Kalman filter is now able to track the target past the occlusion, eliminating the need for using a (more computationally expensive) particle filter.

Unknown motion models: This case could be addressed in principle by performing a purely nonparametric worst-case identification (Parrilo et al. 1999) and then proceeding as above.
Uncertainty and Robustness in Dynamic Vision, Fig. 2 Using the identified model in combination with Kalman filter allows for robust tracking in the presence of occlusion

However, a potential difficulty here stems from the high order of the resulting model (recall that the order of the central interpolant is the number of experimental data points). If a bound n on the order of the underlying models is available, this difficulty can be avoided by recasting the prediction problem into a rank minimization form, which in turn can be relaxed to a semi-definite optimization. To this effect, recall that (Ding et al. 2008), in the absence of noise, given $2n$ values of $\{\mathbf{y}_k\}_{k=t-2n+1}^{t}$, its next value $\mathbf{y}_{t+1}$ is the unique solution to the following rank minimization problem:

$$\mathbf{y}_{t+1} = \underset{\mathbf{y}}{\mathrm{argmin}}\{\mathrm{rank}\,[\mathbf{H}_{n+1}(\mathbf{y})]\} \text{ where } \mathbf{H}_{n+1}(\mathbf{y})$$

$$\doteq \begin{bmatrix} \mathbf{y}_{t-2n+1} & \mathbf{y}_{t-2n+2} & \cdots & \mathbf{y}_{t-n} \\ \mathbf{y}_{t-2n+2} & \mathbf{y}_{t-2n+3} & \cdots & \mathbf{y}_{t-n+1} \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{y}_{t-n+1} & \mathbf{y}_{t-n+2} & \cdots & \mathbf{y} \end{bmatrix} \quad (1)$$

Clearly, the same result holds if multiple elements of the sequence $\mathbf{y}$ are missing, at the price of considering longer sequences (the total number of data points should exceed $2n$). This result allows for handling both noisy and missing data (due, for instance, to occlusion), by simply solving

$$\min_{\boldsymbol{\zeta}} \{\mathrm{rank}\,[\mathbf{H}(\boldsymbol{\zeta})]\} \text{ subject to } \mathbf{v} \in \mathcal{N}_v$$
$$\text{where } \zeta_i = \begin{cases} \mathbf{y}_i - \mathbf{v}_i & \text{if } i \in \mathcal{I}_a \\ \mathbf{x}_i & \text{if } i \in \mathcal{I}_m \end{cases}$$
Uncertainty and Robustness in Dynamic Vision, Fig. 3 Trajectory prediction. Rank minimization (*1*) versus Kalman filtering (*2*)

$\mathcal{I}_a$ and $\mathcal{I}_m$ denote the set of available (but noisy) and missing measurements, respectively, and where $\mathcal{N}_v$ is a set membership description of the noise $\mathbf{v}$. In the case where $\mathcal{N}_v$ admits a convex description, using the nuclear norm as a surrogate for rank (Fazel et al. 2003) allows for reducing this problem to a convex semi-definite program. Examples of these descriptions are balls in ℓ_∞, e.g., $\mathcal{N} \doteq \{v : |v_k| \leq \epsilon\}$ or constraints on the norm of $\mathbf{H}_v$, the Hankel matrix of the noise sequence, which under mild ergodicity assumptions are equivalent to constraints on the magnitude of the noise covariance. Figure 3 illustrates the effectiveness of this approach.

U

As shown there, the rank minimization-based filter successfully predicts the location of the target, while a Kalman filter-based tracker fails due to the substantial occlusion.

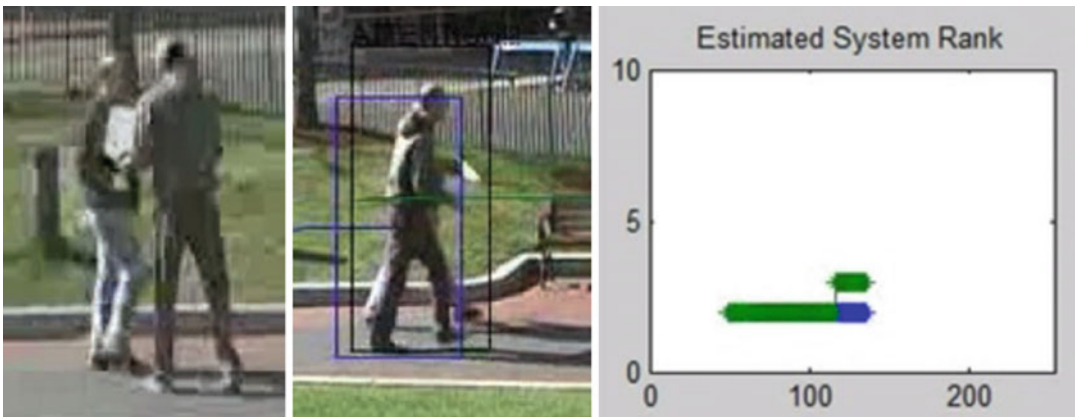
Event Detection and Activity Classification

Using the trajectories generated by the tracking step for activity recognition entails (i) segmenting the data into homogeneous segments each corresponding to a single activity and (ii) classifying these activities, typically based on exemplars from a database of known activities. As shown in the sequel, both steps can be efficiently accomplished by exploiting the properties of the underlying system. The starting point is to model these activities as the output of a switched piecewise linear system. In this context, under suitable dwell time constraints, each switch (indicating a change in the underlying activity) can be identified by simply searching for points associated with discontinuities in the rank of the associated Hankel matrix, as illustrated in Fig. 4. Further, in this framework, the problem of classifying each subactivity can be recast into the behavioral model (in)validation setup shown in Fig. 5. Here $y_i(.)$ represents the impulse response of the (unknown) LTI system G, affected by measurement noise $\eta_i \in \mathcal{N}$ and uncertainty

$\Delta_i \in \mathcal{D}$ that accounts for the variability intrinsic to two different realizations of the same activity. Two different time series are considered to be realizations of the same activity if there exists at least one pair $(\eta_1, \eta_2) \in \mathcal{N}^2$, one pair $(\Delta_1, \Delta_2) \in \mathcal{D}^2$, a LTI system G with McMillan degree at most n_G, and suitable initial conditions $\mathbf{x}_1$, $\mathbf{x}_2$ resulting in the observed data. Remarkably, this model (in)validation problem can be reduced to a rank minimization form. In the simpler case where $\Delta_i = 0$, the problem can be solved using the following algorithm (Sznaier and Camps 2011):

Next, consider the more realistic case where the trajectories are also affected by bounded model uncertainty Δ, $\|\Delta\|_\infty \leq \gamma$, where γ is given as part of a priori information. In this scenario, the internal signal z is given by $z(t) = \zeta(t) - \eta(t)$, $\eta \in \mathcal{N}$, where the signal ζ satisfies

$$y = (1 + \Delta) * \zeta, \text{ for some } \Delta \in \mathcal{D} \qquad (2)$$

where $*$ denotes convolution. Exploiting Theorem 2.3.6 in Chen and Gu (2000) leads to an LMI condition in the variables z, η, for feasibility of (2). Thus, the only modification to Algorithm 1 required to handle model uncertainty is to incorporate this additional (convex) constraint to the rank minimization problems. Table 1 shows the results of applying this approach to


Uncertainty and Robustness in Dynamic Vision, Fig. 4 The jump in the rank of the Hankelmatrix corresponds to the time instant where the subjectsmeet and exchange a bag
Uncertainty and Robustness in Dynamic Vision, Fig. 5 Model (in)validation setup

2 video sequences, walking and running, from the KTH database (Laptev et al. 2008). Sample frames from these sequences are shown in Fig. 6. In order to reduce the dimensionality of the data, the frames were first projected into a three-dimensional space using principal component analysis (PCA), and the resulting time series were used as the input to Algorithm 1, assuming 10 % noise and 10 % model uncertainty. As shown in Table 1, the algorithm correctly identifies the subsequences (a)–(c) as being generated by the same underlying activity (walking).

Data: Noisy measurements y_1, y_2.
A priori information: noise description $\eta_i \in \mathcal{N}$
1. Solve the following rank–minimization problems:
   $r_1^{min} = \min_{\eta_1} \text{rank}(\mathbf{H}_{y_1} - \mathbf{H}_{\eta_1})$
   subject to: $\eta_1 \in \mathcal{N}$.
   $r_2^{min} = \min_{\eta_2} \text{rank}(\mathbf{H}_{y_2} - \mathbf{H}_{\eta_2})$
   subject to: $\eta_2 \in \mathcal{N}$.
   $r_{12}^{min} = \min_{\eta_1} \text{rank}([\mathbf{H}_{y_{1n}}\quad \mathbf{H}_{y_{2n}}])$
   subject to: $\eta_1, \eta_2 \in \mathcal{N}$
   $\mathbf{H}_{y_{1n}} = \mathbf{H}_{y_1} - \mathbf{H}_{\eta_1}$
   $\mathbf{H}_{y_{2n}} = \mathbf{H}_{y_2} - \mathbf{H}_{\eta_2}$
2. The given trajectories were generated by the same LTI system with McMillan degree $\leq n_G$ iff:
   $r_1^{min} = r_2^{min} = r_{12}^{min} \leq n_G$

Summary and Future Directions

Vision-based systems are uniquely positioned to address the needs of a growing segment of the population. Aware sensors endowed with scene analysis capabilities can prevent crime, reduce time response to emergency scenes, and render viable the concept of ultra-sustainable buildings. Moreover, the investment required to accomplish these goals is relatively modest since a large number of cameras are already deployed and networked. Arguably, at this point, one of the critical factors limiting widespread use of these systems is their potential fragility when operating in unstructured scenarios. This article illustrates the key role that control theory can play in developing a comprehensive, provably robust

Underactuated Marine Control Systems

Kristin Y. Pettersen
Department of Engineering Cybernetics,
Norwegian University of Science and
Technology, Trondheim, Norway

Abstract

For underactuated marine vessels, the dimension of the configuration space exceeds that of the control input space. This article describes underactuated marine vessels and the control challenges they pose. In particular, there are two main approaches to design control systems for underactuated marine vessels. The first approach reduces the number of degrees of freedom (DOF) that it seeks to control such that the number of DOF equals the number of independent control inputs. The control problem is then a fully actuated control problem – something that simplifies the control design problem significantly – but special attention then has to be given to the inherent internal dynamics that has to be carefully analyzed. The other approach to design control systems for underactuated marine vessels seeks to control all DOF using only the limited number of control inputs available. The control problem is then an underactuated control problem and is quite challenging to solve. In this article, it is shown how line-of-sight methods can solve the underactuated control problems that arise from path following and maneuvering control of underactuated marine vessels.

Keywords

Marine vessels; Underactuated marine control problems; Underactuated marine vessels; Underactuation

Introduction

Marine systems are often equipped with fewer independent actuators than degrees of freedom. Examples include conventional ships/surface vessels that are typically equipped with a main thruster and a rudder or with two independent main thrusters, but without a side thruster. As a result, we have no control force in the sideways direction. This means that the forward motion (the surge motion) and the orientation (the yaw motion) can be controlled directly, while there is no direct way to influence the sideways motion of the surface vessel (the sway motion). The vessel is then said to be underactuated in sway. It is an underactuated system since it has only two independent control inputs, giving force and torque in surge and yaw, while the system has three degrees of freedom: surge, sway, and yaw. This underactuation leads to challenges when it comes to designing the control system.

Definition: Underactuated Marine Vessels

In order to properly define what we mean by underactuated marine vessels, we need the mathematical model (▶ Mathematical Models of Ships and Underwater Vehicles; Fossen 2011):

$$M\dot{v} + C(v)v + D(v)v + g(\eta) = \begin{bmatrix} \tau \\ 0 \end{bmatrix}$$

$$\dot{\eta} = J(\eta)v$$

where the configuration vector $\eta \in \mathbb{R}^n$, the velocity vector $v \in \mathbb{R}^n$, while the vector of independent control inputs $\tau \in \mathbb{R}^m$. The vessel is underactuated because $n > m$, i.e., the dimension of the configuration space exceeds that of the control input space (Oriolo and Nakamura 1991; Pettersen and Egeland 1996).

The underactuation leads to a second-order nonholonomic constraint

$$M_u\dot{v} + C_u(v)v + D_u(v)v + g_u(\eta) = 0$$

where M_u denotes the last $n - m$ rows of the matrix M and $C_u(v)$, $D_u(v)$, and $g_u(\eta)$ are defined similarly.

Definitions of nonholonomic and holonomic constraints can be found in Goldstein (1980). More facts about these kinds of constraints and conditions for when this second-order nonholonomic can be integrated to either a first-order nonholonomic or a holonomic constraint can be found in Tarn et al. (2003).

Control of Underactuated Marine Vessels

As we have seen above, the underactuation leads to a constraint, and this gives challenges when it comes to designing the control system. In particular, it can be shown that if $g_u(\eta)$ has a zero element, then there exists no continuous or discontinuous state feedback law that can asymptotically stabilize the equilibrium point $(\eta, v) = (0, 0)$ (Pettersen and Egeland 1996). This means

that in order to stabilize an equilibrium point, control methods from linear or classical nonlinear control theory cannot be applied.

There are two main classes of approaches to control underactuated marine vessels. The first class approaches the control problem by reducing the number of degrees of freedom that are to be controlled, while the other class seeks to control all degrees of freedom using the limited number of control inputs available.

If we reduce the number of degrees of freedom (DOF) that we seek to control, such that the number of DOF agrees with the number of independent control inputs, then we have a fully actuated control problem although the vessel is underactuated. This may at first sight look like a very simple way to design a control system for underactuated marine vessels. Note, however, that then, there will inherently be internal dynamics that needs to be examined carefully (Isidori 1995; Nijmeijer and van der Schaft 1990). Say, for instance, that we only care about controlling the position of the ship, and we choose not to care very much about the orientation of the ship. We do, for instance, want the ship to follow a straight line trajectory $(x_r(t), y_r(t))$, where x and y give the ship's position in an earth-fixed coordinate system, and the angle giving the ship orientation, ψ, is not so important to us. It is quite straightforward to use, for instance, output feedback linearization to this end (Isidori 1995; Nijmeijer and van der Schaft 1990). The resulting dynamics of the subsystem (x, y) is then called the external dynamics. We have full control over this using the two independent control inputs and can make it track any smooth trajectory $(x_r(t), y_r(t))$. Everything looks simple when considering the external dynamics only, but the internal dynamics can frequently be hard to predict. The orientation of the ship, given by the yaw angle psi, also needs to be analyzed. The controlled motion will not necessarily have the ship aligned with the tangent of the trajectory, for instance. Firstly, the ship control system that only focuses on the position variables (x, y) may equally well result in the ship moving backward along the line; a behavior that is not really desirable with respect to energy efficiency or for passenger comfort. Secondly,

there will always be environmental disturbances: currents, wind, and waves, and we need to make a thorough stability analysis of the internal dynamics in order to guarantee sufficient robustness properties for these. So to conclude, if you reduce the number of DOF that you seek to control, in order to achieve a fully actuated control problem, then you need to consider the internal dynamics very carefully when dealing with underactuated marine vessels.

If we follow the other approach to controlling underactuated marine vessels, where we seek to control more degrees of freedom than we have independent control inputs, then we not only have an underactuated marine vessel at hand, but we also have an underactuated control problem. This is a challenging control problem, and we will now see how this can be solved for path following and maneuvering control.

Path Following and Maneuvering Control of Underactuated Marine Vessels

For path following control systems, the control objective is to make the vessel follow a given path $\mathcal{P}$, often defined as a parametrized path

$$Y_d := \{y \in \mathbb{R}^m : \exists \theta \in \mathbb{R} \text{ such that } y = y_d(\theta)\}$$

where $m \leq n$ and y_d is continuously parametrized by the path variable θ. The control objective is thus to force the output y to converge to the desired path $y_d(\theta)$: $\lim_{t \to \infty} |y(t) - y_d(\theta(t))| = 0$. This constitutes a geometric task. When there is also a dynamic task, for instance, a speed assignment like forcing the path speed $\dot{\theta}$ to converge to a desired speed $v_s(\theta(t), t)$

$$\lim_{t \to \infty} |\dot{\theta}(t) - v_s(\theta(t), t)| = 0$$

then the control problem is an output maneuvering problem (Skjetne et al. 2004).

Line-of-sight (LOS) guidance control has proven to be a powerful tool for path following and maneuvering control of underactuated vessels. LOS guidance is much used in practice for manual control of ships, where the helmsman typically will steer the vessel toward a point lying a constant distance, called the look-ahead distance, ahead of the vessel along the desired path. LOS guidance is simple, intuitive, and easy to tune, and it can be shown that it provides nice path convergence properties (Breivik and Fossen 2004; Børhaug et al. 2008; Caharija et al. 2012; Fredriksen and Pettersen 2006; Lefeber et al. 2003). For the simplified case without any environmental disturbances and when the desired path is a straight line, the LOS guidance law for an underactuated surface vessel is given by

$$\psi_d = \psi_{\text{LOS}} = -\tan^{-1}\left(\frac{y}{\Delta}\right), \quad \Delta > 0$$

where y is the cross-track error. The angle ψ_{LOS} is called the line-of-sight (LOS) angle, and geometrically, it corresponds to the orientation of the vessel when headed toward the point that lies a distance $\Delta > 0$ ahead of the vessel along the path $y = 0$, cf. Fig. 1. The look-ahead distance Δ is a control design parameter.

In order to handle ocean currents and other environmental disturbances such as wind and waves, the LOS guidance law can be extended with integral action

$$\psi_{\text{LOS}}^m = -\tan^{-1}\left(\frac{y + \sigma y_{\text{int}}}{\Delta}\right), \quad \Delta > 0$$
$$\dot{y}_{\text{int}} = \frac{\Delta y}{(y + \sigma y_{\text{int}})^2 + \Delta^2}$$
Underactuated Marine Control Systems, Fig. 1 Illustration of LOS guidance

where $\sigma > 0$ is a design parameter, an integral gain, and $\Delta > 0$ has the same interpretation as above. The integral effect will generate a sideslip angle that allows the vessel to stay on the desired path even though affected by environmental disturbances with components normal to the path, even though the vessel has no control forces to act in the sideways direction.

Various standard control techniques can readily be used to track the above guidance commands. LOS guidance can also be extended to the 3D case for path following/maneuvering control of underactuated autonomous underwater vehicles (AUV), cf. the references given above.

Summary and Future Directions

Underactuated marine vessels are vessels for which the dimension of the configuration space exceeds that of the control input space. There are two main approaches to design control systems for underactuated marine vessels. The first approach reduces the number of degrees of freedom (DOF) that it seeks to control, such that the number of DOF equals the number of independent control inputs. The control problem is then a fully actuated control problem, something that simplifies the control design problem significantly, but special attention then has to be given to the inherent internal dynamics that has to be carefully analyzed. The other approach to design control systems for underactuated marine vessels seeks to control all DOF using only the limited number of control inputs available. The control problem is then an underactuated control problem, and this is a quite challenging control problem. In this entry, it is shown how line-of-sight methods can solve the underactuated control problems that arise from path following and maneuvering control of underactuated marine vessels.

Future developments of underactuated marine control systems will include solving more underactuated control problems of marine vessels taking into account both the complete mathematical model of the vessels and also advanced mathematical models of all the environmental disturbances in both 2D and 3D.

Underactuated Robots

Kevin M. Lynch
Mechanical Engineering Department,
Northwestern University, Evanston, IL, USA

Abstract

Underactuated robots, robots with fewer actuators than degrees of freedom, are found in many robot applications. This entry classifies underactuated robots according to their dynamics and constraints and provides an overview of controllability, stabilization, and motion planning.

Keywords

Nonholonomic constraints; Nonlinear control; Underactuation

Introduction

An *underactuated robot* is a robot with fewer actuators (control inputs) than the number of variables describing its configuration (degrees of freedom). Some robots have this property unavoidably, while others are specifically designed this way, perhaps to save the cost of actuators. Examples include:

- **A cart and pendulum (inverted pendulum).** This system has two degrees of freedom, the linear position of the cart and the angle of the pendulum, but only one control input, the acceleration of the cart.

- **A car.** A car has only two control inputs (steering and forward/backward speed) but at least three degrees of freedom: the position (x, y) and orientation θ of the chassis. If the steering and/or rolling angles of the wheels are included in the representation of the configuration, the car has even more degrees of freedom.

- **A walking robot.** When a biped steps with one foot in the air and the toes of the other foot on the ground, there is no actuator at the toes to directly control the angle between the foot and the ground.

- **A quadrotor flying robot.** A quadrotor has four control currents driving the four propellers, but its configuration is described by six variables: (x, y, z) position and roll, pitch, and yaw.

- **An underactuated robot hand.** Robot hands generally have many joints, up to four per finger for anthropomorphic hands. To reduce cost, a small number of motors (as few as one) may be used to open and close the fingers, with joint motions coupled by springs.

- **Robot manipulation.** When a robot arm and hand manipulates a rigid object, the entire system, taken together, has at least six more degrees of freedom than actuators – the six degrees of freedom of the object.

In all underactuated robot systems of interest, the fewer control inputs are somehow coupled to all of the degrees of freedom. This entry focuses on coupling through the inertia matrix and kinematic constraints. In addition, this entry

U

focuses on control of the full configuration, or more generally the state, of the robot system. Other goals, such as successfully grasping an object with a compliant underactuated hand, are outside the scope of this entry.

Classification of Underactuated Robots

The robot has n degrees of freedom, and its configuration is written in local coordinates as a column vector $q \in \mathbb{R}^n$. If the robot is described as a *kinematic* system, then its state x is simply q and the control inputs are velocities. If the robot is a *mechanical* system, then its state is $x = [q^T, \dot{q}^T]^T$ and the control inputs are accelerations (forces). Let p denote the dimension of the state space, where $p = n$ for a kinematic system and $p = 2n$ for a mechanical system.

The equations of motion of an underactuated robot can be written in the control-affine form

$$\dot{x} = f(x) + \sum_{i=1}^{m} u_i g_i(x) \quad \text{where } m < n. \quad (1)$$

The vector field $f(x)$ is a *drift vector field* describing the unforced motion of the robot, the $g_i(x)$ are linearly independent *control vector fields* describing how the controls act on the robot, and $u = [u_1, \ldots, u_m]^T$ is the control. Kinematic systems are commonly *drift-free* ($f(x) = 0$). For a mechanical system, the drift field $f(x)$ typically includes velocities acting on positions and gravity acting on velocities.

The fact that the number of controls m is less than the number of degrees of freedom n can be viewed as $n - m$ constraints on the motion. For a kinematic system, these are velocity constraints. For a mechanical system, these are acceleration constraints. In addition, a mechanical system may be subject to a separate set of k velocity constraints, often called *Pfaffian* constraints, of the form

$$A(q)\dot{q} = 0, \quad (2)$$

where $A(q) \in \mathbb{R}^{n \times k}$. Such constraints arise from conservation laws and rolling without slip, for example.

Understanding the integrability of these constraints is key to understanding the controllability of underactuated robots (section "Determining Controllability"). For example, if acceleration constraints can be integrated to yield equivalent velocity constraints, then the dimension of the space of reachable velocities of the mechanical system is reduced. If velocity constraints can be integrated to yield equivalent configuration constraints, then the dimension of the reachable configuration space is reduced. If some velocity constraints are integrable to configuration constraints, we simply eliminate those configuration variables from the description of the system so we can focus on the controllable degrees of freedom. Velocity constraints that cannot be integrated are called *nonholonomic*, while configuration constraints are called *holonomic*.

Based on the type of constraints, we can classify underactuated robots into three categories – pure kinematic, pure mechanical, and mixed kinematic and mechanical – as described below.

Pure Kinematic

This category consists of systems with velocities as inputs, as well as mechanical systems that can be modeled by a *kinematic reduction* that has time-differentiable velocities as controls (Bullo and Lewis 2004; Bullo et al. 2002). (The actual acceleration controls of the original system are the time derivatives of these velocities.) Examples of mechanical systems that can be reduced to kinematic systems include systems with actuators for every degree of freedom (fully actuated systems, of little interest here) and mechanical systems whose acceleration constraints can be completely integrated to equivalent velocity constraints.

Example 1 (Upright rolling wheel) Consider a wheel of radius R rolling upright on a horizontal plane (Fig. 1a). The center of the wheel is (p_x, p_y, p_z), and the orientation is described by its "leaning" angle θ, rolling angle ψ, and heading angle ϕ. The constraints that the wheel
remain upright and touching the plane can be
written differentially as $\dot{p}_z = 0$ and $\dot{\theta} = 0$,
but these constraints can be integrated to the
equivalent configuration constraints $p_z = R$ and
$\theta = 0$, so we eliminate these variables from the
description of the configuration and focus on the
remaining four coordinates.

Writing the configuration vector as $q = [p_x, p_y, \psi, \phi]^T$ and the two control inputs as
the rolling velocity $u_1 = \dot{\psi}$ and the heading rate
of change $u_2 = \dot{\phi}$, the control system is

$$\dot{q} = u_1 g_1(q) + u_2 g_2(q),$$

where $g_1(q) = [R\cos\phi, R\sin\phi, 1, 0]^T$ and
$g_2(q) = [0, 0, 0, 1]^T$. Implicit in these equations
of motion are the two rolling constraints
$A(q)\dot{q} = 0$, where

$$A(q) = \begin{bmatrix} 1 & 0 & -R\cos\phi & 0 \\ 0 & 1 & -R\sin\phi & 0 \end{bmatrix}.$$

These velocity constraints cannot be integrated to
equivalent configuration constraints.

Example 2 (Reaction-wheel satellite) The three-
dimensional orientation of a satellite can be con-
trolled by spinning internal reaction wheels. The
controls to the reaction wheels are torques. By
conservation of angular momentum, the total an-
gular momentum P of the satellite is subject to
the constraints

$$P = J\omega + \sum_i J_i \omega_i = \text{constant},$$

where J is the inertia of the satellite body, ω is its
angular velocity, J_i is the inertia of momentum
wheel i, and ω_i is its angular velocity. These
constraints are velocity constraints – given the
angular velocity of the momentum wheels, the
angular velocity of the satellite is known. Thus,
we can treat the original mechanical system as
a kinematic system with (differentiable) angular
velocities of the momentum wheels as inputs.
If the system satisfies $P = 0$, the kinematic
reduction is drift-free.

While satellite orientation is commonly
controlled using three orthogonal reaction
wheels (a fully actuated system), two reaction
wheels suffice to control the orientation of
the kinematic reduction in the case $P = 0$.
This is apparent from the fact that successive
rotations about two orthogonal body-fixed axes
(e.g., body-referenced ZYZ Euler angles) are
sufficient to arbitrarily orient a rigid body in
space.

Pure Mechanical

This category consists of mechanical systems
without any velocity constraints.

Example 3 (3R robot arm with a passive joint)
The dynamics of a robot arm are determined by
its inertia matrix $M(q)$, from which the kinetic
energy $K = \frac{1}{2}\dot{q}^T M(q)\dot{q}$ is derived, and its
potential energy $V(q)$. If one of the joints of the
arm rotates freely without an actuator, the arm
is underactuated. One such robot is a planar arm
with two actuated joints and one passive (Bullo
and Lynch 2001; Lynch et al. 2000). For this

robot, the acceleration constraint arising from the lack of an actuator cannot be integrated to an equivalent velocity constraint.

Mixed Kinematic and Mechanical

This category consists of mechanical systems with both (1) velocity constraints and (2) acceleration constraints that cannot be integrated.

Example 4 (Snakeboard) The snakeboard is a skateboard with steerable wheels. The rider can locomote without touching the ground by twisting his or her body while steering the wheels. The configuration of a robotic model of the snakeboard and rider (Ostrowski et al. 1994) consists of the position (x, y) and orientation θ of the board, the steering angle of the wheels (assumed to be coupled to be equal and opposite), and the angle of a reaction wheel representing the rider (Fig. 1b). The controls are the steering torque to the wheels and the driving torque of the reaction wheel. This system is mixed because of the presence of the no-slipping constraint at the wheels.

While in some cases it is obvious whether velocity or acceleration constraints can be integrated to equivalent constraints on configuration or velocity, respectively, in general this is not trivial. Instead of attempting to determine the integrability of constraints, we typically study the reachable sets of the system (1). This is the topic of controllability of nonlinear systems, section "Determining Controllability".

Underactuated robots can also be classified according to the set of available controls $\mathcal{U} \subseteq \mathbb{R}^m$. For example, the control set could be a discrete set of points in $\mathbb{R}^m$, or only nonnegative values, or a bounded set of $\mathbb{R}^m$ containing the origin in the interior. For simplicity, assume $u \in \mathcal{U} = \mathbb{R}^m$.

Control Challenges

Determining Controllability

For linear systems of the form $\dot{x} = Ax + Bu$, $x \in \mathbb{R}^p$, $u \in \mathbb{R}^m$, there is one notion of controllability, determined by the Kalman rank condition (KRC). If the rank of the matrix

$$[B \ \ AB \ \ A^2 B \ \ \dots \ \ A^{p-1}B]$$

is p, then it is possible to transfer the system from any state to any other state in finite time.

Most underactuated systems of the form (1), such as all of the examples given above, are non-linear systems, however. For nonlinear systems, there are many possible notions of controllability (see Bullo and Lewis 2004; Lynch et al. 2011; Nijmeijer and van der Schaft 1990; Sussmann 1983). Some examples include:

- *Small-time local accessibility (STLA) at x*: For any time $T > 0$, the reachable set starting from x at times $t < T$ contains a full-dimensional subset of the state space.
- *Small-time local controllability (STLC) at x*: For any time $T > 0$, the reachable set starting from x at times $t < T$ contains a neighborhood of x.
- *Global controllability*: The robot can reach any state from any other state.

STLC is strictly stronger than STLA. Neither implies global controllability nor does global controllability imply either of the local properties. STLA and STLC are illustrated in Fig. 2.

STLA can be tested by a Taylor expansion of flows along vector fields. A key object in this study is the *Lie bracket* of two vector fields $V_1(x)$ and $V_2(x)$, defined as the new vector field

$$[V_1, V_2] = \frac{\partial V_2}{\partial x} V_1 - \frac{\partial V_1}{\partial x} V_2.$$

If the system were to start from x and flow along V_1 for a short time ϵ, then V_2 for ϵ, then $-V_1$ for ϵ, then $-V_2$ for ϵ, a Taylor expansion shows that the net motion of the system would be $\epsilon^2 [V_1, V_2](x)$ (plus terms of order ϵ^3 and higher). If this direc-
Underactuated Robots, Fig. 2 Example reachable sets in small time for systems that are STLA and STLC at x

tion is neither zero nor a linear combination of V_1 and V_2, then effectively a new motion direction has been created.

For the upright rolling wheel, the Lie bracket of g_1 (forward-backward rolling) and g_2 (turning) is

$$[g_1, g_2] = [R \sin \phi, -R \cos \phi, 0, 0]^T,$$

a sideways "parallel parking" motion. This new direction increases the dimension of the locally reachable set beyond what could be reached by a local linearization of the nonlinear system.

Roughly speaking, the *Lie algebra* of a set of vector fields $\mathcal{V}$ is the set of vector fields $\mathcal{V}$, all iterated Lie brackets of these vector fields, and their linear combination. For example, the Lie algebra of $\mathcal{V} = \{g_1, g_2\}$ includes $[g_1, g_2]$, $[g_1, [g_1, g_2]]$, $[g_2, [g_1, [g_1, g_2]]]$, etc., as well as their linear combinations. Deeper Lie brackets correspond to higher-order terms in the Taylor expansion of flows.

With these concepts, a theorem due to Chow (1939) says that a system (1) satisfies STLA at x if the dimension of the Lie algebra of $\{f, g_1, \ldots, g_m\}$ at x is p, the dimension of the state space. This is known as the *Lie algebra rank condition* (LARC). Most underactuated systems of interest satisfy the LARC but not the KRC. For the upright rolling wheel, the linearization at any q fails the KRC, but the four-dimensional configuration space is spanned by g_1, g_2, $[g_1, g_2]$, and $[g_2, [g_1, g_2]]$ at all q, satisfying the LARC. Therefore the system is STLA at all points.

The STLA property can be strengthened to STLC if the system additionally satisfies certain symmetry properties, allowing it to proceed both forward and backward along Lie bracket directions. For example, if $f(x) = 0$ and the control set $\mathcal{U}$ contains the origin in the interior, the LARC implies STLC. This is the case for the upright rolling wheel. More general notions of symmetry have also been derived (e.g., Sussmann 1987).

For mechanical systems, STLC can only hold at zero-velocity states where $f(x) = 0$. In addition, velocity constraints may prevent the system from reaching a $2n$-dimensional set in state space. A more relevant question may be whether the configuration alone can be locally controlled at zero-velocity states. Specialized Lie-algebraic controllability tests have been developed for configuration controllability of mechanical and mixed systems (Bullo and Lewis 2004; Bullo and Lynch 2001; Bullo et al. 2002; Lewis 2000).

Global controllability results often derive from STLC at all states for drift-free systems or from STLA and global properties of the vector fields or the topology of the state space (Choset et al. 2005).

Feedback Stabilization

For some underactuated robots, the linearization at a state x may satisfy the KRC. An example is an inverted pendulum linearized at a balanced equilibrium state. In this case, it is possible to derive a linear feedback controller, based on the linearization, to stabilize the balanced state.

For many underactuated systems of interest, however, the linearization at a desired state is not controllable. For such systems, a famous theorem due to Brockett (1983), plus subsequent strengthening, implies the following:

Theorem 1 *For any drift-free underactuated kinematic system of the form* (1)*, there exists no time-invariant continuous state feedback law that stabilizes the origin.*

For example, there exists no continuous state-feedback control law that can stabilize the upright rolling wheel to a desired configuration.

This obstruction to stabilizability has resulted in a number of different approaches to feedback control of underactuated systems, including (1) time-varying feedback control laws, (2) feedback control laws that are discontinuous in the state, and (3) two-degree-of-freedom controllers consisting of a motion planner plus a feedback controller for the easier problem of stabilizing the nominal trajectory. Strategies for planning nominal motions for two-degree-of-freedom controllers are discussed next.

Motion Planning

Given an initial state $x(0) = x_{\text{start}}$ and a goal state x_{goal}, the motion planning problem for a

system $\dot{x} = h(x, u)$ is to find a control history $u : [0, T] \rightarrow \mathcal{U}$ such that

$$x_{\text{goal}} = x_0 + \int_0^T h(x(s), u(s)) ds$$

while avoiding any obstacles that may be present in the environment. It may also be desired to minimize some notion of cost,

$$J = \int_0^T L(x(s), u(s)) ds.$$

One choice of $L(s)$ is $u^T(s)u(s)$, the square of the control effort.

Ideally the motion planning method would be *complete* (guaranteed to find a solution in finite time if one exists) or *probabilistically complete* (if a solution exists, the probability of finding a solution goes to one as time goes to infinity).

A variety of approaches to motion planning have been proposed in the robotics literature. Approaches that apply to underactuated systems include:

- *Search-based methods.* A popular class of search-based methods are rapidly exploring random trees (RRTs) and variants (LaValle and Kuffner 2001). These approaches offer probabilistic completeness for many systems, including systems with obstacles, but naïve implementations may be slow to find solutions, and the solutions generally do not satisfy optimality criteria.

- *Numerical optimization.* The control history can be converted to a finite parameterization using representations such as polynomials, cubic B-splines, wavelets, and truncated Fourier series. Numerical optimization methods can then be applied to solve the two-point boundary value problem while minimizing a cost function. Gradient-based numerical optimization methods may yield locally optimal solutions, but they may suffer from numerical convergence problems, and they may get stuck in local minima depending on an initial guess. Optimization methods that do not use gradient information potentially offer globally optimal

solutions, but typically at the expense of significantly longer computation times.

- *Fictitious input methods.* These methods assume that there is a direct control input available for each Lie bracket motion direction. These fictitious inputs are then converted to a sequence of feasible inputs utilizing the Campbell-Baker-Hausdorff-Dynkin expansion of flows (Lafferriere and Sussmann 1991). In general, these methods require iterative application to account for errors in the approximate conversion.

- *Trajectory transformation methods.* One way to deal with obstacles is to first use a global motion planner that is complete under the assumption that the robot has no motion constraints. Then the template unconstrained solution is iteratively subdivided into smaller pieces, with each piece replaced by an obstacle-free feasible trajectory generated by a local planner. If the system is drift-free and STLC at all configurations, then it is possible to develop a local planner that guarantees success of the transformation from an unconstrained trajectory to a feasible trajectory as the subdivisions get small enough (Laumond et al. 1994).

Often it is possible to exploit structure of the equations of motion beyond the general form (1). Making use of extra structure can reduce the computational complexity of motion planning.

- *Chained form, sinusoidal controls, and averaging.* Certain drift-free kinematic systems can be transformed to a canonical *chained form*. For systems in such a form, sinusoidal controls of integrally related frequencies can be chosen to drive one of the configuration variables to its desired value while having zero net effect on configuration variables already at their desired value. In this way, configuration variables can be driven sequentially to their desired values (Murray and Sastry 1993).

For many underactuated systems, sinusoidal controls can be used to achieve approximate motion in each Lie bracket direction needed to complete the LARC. The resulting periodic motions are sometimes called *gaits*, and motion planning can be

achieved using a finite set of gaits (Bullo and Lewis 2004; Ostrowski et al. 1994).

- *Differentially flat systems.* For certain underactuated systems with $u \in \mathbb{R}^m$, there exist a set of m functions w_i of the state, the control, and its derivatives,

$$w_i(x, u, \dot{u}, \ddot{u}, \ldots, u^{(r)}), \quad i = 1 \ldots m,$$

such that the states and control inputs can be expressed as functions of w and its time derivatives. The w_i are called *flat outputs*. The motion planning problem is to find $w(t), t \in [0, T]$, such that $w(0), \dot{w}(0), \ddot{w}(0), \ldots$ and $w(T), \dot{w}(T), \ddot{w}(T), \ldots$ satisfy the constraints specified by x_{start} and x_{goal}. The problem changes from constrained motion planning in the p-dimensional state space to finding a curve satisfying start and end constraints on w and its derivatives (Fliess et al. 1995; Sira-Ramirez and Agrawal 2004).

- *Kinematic reductions.* Motion planning in configuration space is a lower-dimensional problem than motion planning in configuration-velocity space. Therefore, when a mechanical system can be reduced to a kinematic equivalent, motion planning can be more efficient. Examples include mechanical systems that can be fully reduced to a kinematic system (like the reaction-wheel satellite) and mechanical systems that admit rank-1 kinematic reductions – vector fields on configuration space that can be followed at any speed, despite the underactuation constraints. These vector fields become primitives for motion planning on configuration space (Bullo and Lewis 2004; Bullo and Lynch 2001; Bullo et al. 2002; Choset et al. 2005).

Summary and Future Directions

Underactuated systems arise in all areas of robotics, including robot manipulation and aerial, ground, and underwater locomotion. Underactuation raises a number of challenging issues in robot motion planning and control.

While significant progress has been made, further research is needed on computationally efficient motion planning and robust stabilization of nominal trajectories. In addition, although this entry focuses on systems that can be described by a single set of dynamics, many interesting underactuated systems are hybrid systems that experience changing contact constraints. Examples include biped robots striding from one foot to the next and robot manipulators that manipulate objects with changing contact modes (grasping, rolling, pushing, etc.). Further work is needed to incorporate contact models, beyond simple kinematic constraints, and changing equations of motion in motion planning and control of hybrid underactuated systems.

Recommended Reading

Introductions to underactuated robot systems can be found in Choset et al. (2005), Lynch et al. (2011), and Murray et al. (1994).

While this entry focuses on configuration spaces modeled locally as $\mathbb{R}^n$, most robotic systems consist of rigid bodies whose positions and orientations can be described globally as elements of the Lie group $SE(3)$ or one of its subgroups: $SE(2)$, $SO(3)$, or $SO(2)$. Geometric methods for control of underactuated systems make use of the extra structure of Lie groups and their Lie algebras, symmetries, and concepts

from geometric mechanics such as tangent and cotangent bundles, Riemannian metrics on manifolds, symplectic manifolds, connections, fiber bundles, covariant derivatives, etc. Excellent treatments can be found in Bloch et al. (2003), Bullo and Lewis (2004), and Murray et al. (1994).

Abstract

Validation and verification (V&V) of advanced control systems is required for their use in fielded systems. A comprehensive V&V process involving analysis, simulation, and experimental testing should be used to assess closed-loop system performance and identify system limitations. This entry discusses current V&V methods and tools as well as future research directions for safety-critical control applications.

Keywords

Closed-loop system stability and performance; Software Verification; Stability and performance robustness; Uncertainties and uncertainty models; Validation of Safety-Critical Systems

Introduction

Control system validation and verification (V&V) is an assurance that the closed-loop system (i.e., the control system acting on the plant being controlled) remains stable and performs within acceptable performance metrics across the operational region of application. Basic definitions of validation and verification are given below (IEEE 2011).

Validation: The assurance that a product, service, or system meets the needs of the customer and other identified stakeholders. It often involves acceptance and suitability with external customers.

Verification: The evaluation of whether or not a product, service, or system complies with a regulation, requirement, specification, or imposed condition. It is often an internal process.

Control system validation can therefore be thought of as a confirmation that the algorithms are performing their intended functions and an affirmation of their effectiveness in performing these functions. Validation is a rigorous evaluation process that should involve clearly identifying system limitations, including regions of operation within which stability or acceptable levels of performance are not guaranteed. Verification can be thought of as a confirmation that the system implementation in software and hardware is correctly executing the algorithms as designed (and validated). This includes a rigorous evaluation of system requirements and specifications and a clear determination of whether or not they have been met. V&V methods include analysis, simulation, and experimental testing, which are (ideally) applied in an integrated or iterative manner to corroborate results across methods of

evaluation. In the case of aircraft flight control and other safety-critical control applications, the V&V process must ultimately lead to system certification. The following subsections summarize control system V&V analytical, simulation, and experimental test methods in terms of the current (or recommended) state of practice. A summary and some future research directions for safety-critical control applications are also provided.

Control System Validation

Validation methods, involving analysis, simulation, and experimental testing, are utilized to ensure against errors and significant deficiencies in the underlying control system algorithms under realistic operational conditions for the intended application. System weaknesses and limitations are also identified through the validation process. Control system validation begins with an analysis of closed-loop system stability, performance, and robustness. Linear systems theory forms the basis for analytical stability and robustness methods and the associated software tools that are currently available for closed-loop system validation. In current practice, stability of nonlinear systems is determined by evaluating the stability of the linearized closed-loop system at numerous equilibrium points across the operating range (or envelope) of the system. Closed-loop stability is assessed by computing the eigenvalues of the linearized closed-loop system at a number of equilibrium points in the region of operation. It should be noted, however, that stability is not guaranteed between the operating points analyzed. Moreover, if the control system utilizes gain scheduling across the operating envelope, stability cannot be guaranteed for interpolated gains between the design points. Relative stability is determined by gain and phase margins for single-input, single-output (SISO) systems and by the multivariable stability margin (see, e.g., Lavretsky and Wise 2013) for multiple-input, multiple-output (MIMO, or multivariable) systems. Time-delay margins, defined as the minimum time delay required to destabilize the closed-loop system, can be determined from

phase margin and verified in nonlinear simulation. Stability robustness is assessed in terms of uncertainties, including parametric uncertainties and unmodeled dynamics in the mathematical model of the plant. Advanced robustness analysis methods based on the structured singular value (Zhou et al. 1996) require the uncertainties to be separated from the nominal plant into what is termed a linear fractional transformation (LFT). Advanced robustness methods can be used to assess stability and performance robustness, as well as worst-case combinations of uncertainties that result in destabilization, loss of performance, or the lowest robustness margins. LFT models can be formulated for the analysis of nonlinearities, expressed as multivariate polynomials, around a trim condition or over subregions within the operational envelope. Stability over a region or subregion of the operating envelope can be guaranteed using linear parameter-varying (LPV) methods (see Apkarian and Gahinet 1995; Packard 1994; Rugh and Shamma 2000; Wu et al. 1996). Nonlinear stability and control are addressed more fully in Slotine and Li (1991) and Khalil (2002), as well as in numerous other texts. Analytical methods and software tools are available in Matlab®, using the Control System Toolbox™ and Robust Control Toolbox™. LFR/LFT modeling methods and software tools are described in Magni (2004, 2006), Hecker et al. (2005), Varga et al. (1998), and Belcastro et al. (2005) and provided in the Robust Control Toolbox®. An LPV Toolbox™ is also under development and will become available soon (see Balas et al. 2013b).

Performance is usually assessed using a high-fidelity simulation of the plant under expected operational conditions. The simulation should include nonlinear plant dynamics, noise, disturbances, and any other phenomena anticipated under operation. Nominal performance is assessed in terms of the control system design objectives, which typically include (at a minimum) closed-loop steady-state tracking and transient response characteristics. Transient response characteristics typically include delay time, rise time, peak time, maximum overshoot, and settling time (see, e.g., Ogata 1970). Steady-state tracking error is also

typically assessed. Performance robustness can be evaluated using Monte Carlo simulation techniques (see, e.g., Kroese et al. 2011), in which parameters and operational conditions are varied over numerous simulation runs in order to statistically evaluate an extensive set of uncertainties and operational variations. Stability robustness can also be assessed using Monte Carlo simulation techniques and by utilizing worst-case uncertainties and time-delay margins obtained during analysis. If the plant is a vehicle or robotic manipulator to be operated by a human, the handling qualities must also be evaluated to assess human-system interfaces and interactions. A real-time high-fidelity simulation with a human interface representative of the operational environment is required for this evaluation. For aircraft, piloted simulation evaluations are conducted using a cockpit mock-up, and handling qualities are assessed under various scenarios using the Cooper-Harper Scale (Cooper and Harper 1969). Susceptibility to operator-induced oscillations, for example, resulting from time delays in the controlled response, may typically be uncovered using operator-in-the-loop simulation evaluations.

Experimental testing should be conducted under realistic conditions that cover the entire (potential) operational space of the plant being controlled in order to assess realistic operational performance. For aircraft, this includes flight testing using full-scale and/or subscale test vehicles under nominal and off-nominal conditions. If the analytical and simulation evaluations provide a good match to the experimental evaluations, the test matrix can be comprised of key high-risk conditions to confirm desired behavior.

Validation methods should be applied in an iterative manner comparing results from the analysis, simulation, and experimental tests and going back to reevaluate in one domain based on results from another. For example, analysis results should provide good predictions of results seen in simulation and experimental testing. If a good match is not obtained, the analysis model may have to be improved or another analysis method

utilized to reduce conservatism in the result. Similarly, simulation results should provide a good prediction of experimental test results.

Control System Verification

System verification is ideally performed by or in collaboration with a computer science specialist to ensure against errors in the software/hardware implementation of the control algorithms. Control system verification begins with an analysis (Rushby 1995, 2009) of the software and hardware implementation requirements to ensure completeness and accuracy in the system specification. Several refinement steps are taken to transform the control system requirements to those implementable on the actual avionics hardware to be fielded. Verification, consisting of tests and analyses, is required to confirm requirements traceability and compliance from one refinement to another, to confirm accuracy of the algorithms, and to assure compliance and robustness of the final code with respect to the original control algorithms, to ensure that no errors are introduced from the refinement itself or related to the target computing platform. Formal analysis methods can be used to evaluate software logic and other software mechanisms for correctness under all operational conditions and to provide correctness proofs. Formal methods can also be utilized for model checking to verify system properties through an exhaustive search of all possible states that can be entered during execution (Berard et al. 1998). One software verification tool is called PVS (Owre et al. 1992), developed by SRI International, and is available on the Internet as an open-source software tool. Other methods and tools are also available from SRI International, as well as other sources.

Simulation techniques are used to evaluate software code, modules, subsystems, and the full system. Once the software has been verified, it is implemented on actual or representative hardware and evaluated using hardware-in-the-loop simulation and experimental testing. Experimental testing should include laboratory evaluations under all possible operational conditions and in

a relevant application environment. For aircraft, this would include flight testing of the control system on the actual avionics hardware to be fielded.

Summary and Future Directions

This entry has summarized current and recommended practices for control system V&V, including methods and tools for analysis, simulation, and experimental testing. The V&V process ensures against errors and deficiencies in the underlying system algorithms (validation) and in its software/hardware implementation (verification). Analysis, simulation, and experimental testing are performed iteratively to utilize and confirm results between evaluation techniques.

A comprehensive validation process is performed to assure control system effectiveness across the operational envelope of the plant and to identify system limitations and weaknesses. Current analysis methods for control system validation are typically based on linear systems theory and focus on nominal operations under model uncertainties and anticipated disturbances (e.g., noisy measurement signals). This analysis includes stability, performance (e.g., tracking accuracy), and robustness. Advanced robust control analysis methods have been applied to safety-critical applications, such as aircraft (see Fielding et al. 2002; Varga et al. 2012), to assess robust stability and performance. These two references provide a global optimization-based worst-case approach as a "necessary condition" technique for flight control system validation or as a "sufficient condition" technique for invalidation. High-fidelity nonlinear simulation evaluations are performed in batch and real time to assess robustness under system and operational uncertainties and to assess interface effectiveness for human-in-the-loop operations (if applicable). Experimental testing under realistic operationally relevant conditions is performed across key operating conditions to confirm analytical and simulation predictions.

System verification is performed to ensure correctness of the hardware/software implementation. Various analysis and testing methods, including advanced formal analysis methods, are used to assess completeness of the system requirements and specification and software elements (e.g., logic). Model checking techniques are used to verify system properties. Code is tested in simulation and on representative or actual hardware under realistic operationally relevant conditions.

Future research directions will enable the V&V of nonlinear and adaptive control systems (see, e.g., Hovakimyan and Cao 2010; Tallant et al. 2004) that improve performance under highly uncertain conditions, as well as the V&V of complex integrated safety-critical systems for operation under off-nominal and hazardous conditions (see Belcastro 2010, 2012). These systems will include diagnostic and prognostic algorithms for integrated vehicle health management, resilient control systems that enable the detection and mitigation of multiple hazards, supervisory systems that provide safety assurance (for safety-critical operations), and intelligent interface and decision-based systems that enable human-optional and fully autonomous operations. These systems will inherently involve stochastic decision-making and nonlinear and adaptive control algorithms. V&V of these future systems poses significant technical challenges and is the subject of current research. Some of these challenges include the following: (1) development and validation of multidisciplinary simulation models for characterizing hazardous condition effects; (2) validation of adaptive, diagnostic/prognostic, and reasoning algorithms under numerous off-nominal and hazardous conditions; (3) verification of software-intensive highly complex systems; and (4) determining a level of confidence in V&V results for hazardous application domains that cannot be fully replicated during the evaluations.

Research on modeling and simulation methods is being performed to characterize multidisciplinary effects of off-nominal and hazardous conditions, and validation of these models can be difficult. For aircraft applications, hazardous

conditions relate to aircraft loss of control (LOC) and precursor conditions. LOC is a complex and highly nonlinear phenomenon for which there is little available data. Hazardous conditions considered in this research include vehicle upset conditions (e.g., stall/departure), vehicle impairment conditions (e.g., failure, icing, and damage), and external disturbances (e.g., inclement weather and wake vortices). Multidisciplinary models under development include aerodynamic, propulsion, and airframe structure effects. For example, simulation models for characterizing aircraft flight dynamics and control effects under upset conditions are currently being developed (see, e.g., Foster et al. 2005; Groen et al. 2012), as well as propulsion effects resulting from the associated reduced flow conditions (Liu et al. 2013). Model validation is being performed using available flight and accident data, as well as experimental testing in the laboratory and through subscale and full-scale flight testing. The enhanced high-fidelity simulation models resulting from this research will be used in the development and validation of onboard control systems designed to detect and mitigate these hazards.

Current research efforts for validating the above future systems include nonlinear robustness analysis methods and software tools (see (Chakraborty et al. 2011a, b), Balas et al. 2013a; Packard et al. 2010; Summers et al. 2013), nonlinear analysis methods for controlled systems (Gill et al. 2012; Kwatny et al. 2013), uncertainty quantification and robustness analysis methods for mixed uncertainties and multiple objectives (Kenny et al. 2012), and the analysis of stochastic filters (see, e.g., Reif et al. 1999; Rhudy et al. 2013a, b, c). The term "mixed uncertainty" refers to aleatory and epistemic uncertainties. Aleatory uncertainties are typically stochastic (or statistical) and represent operational or environmental uncertainties (e.g., turbulence) that cannot be altered or controlled during experiments or fielded applications. Epistemic uncertainties are typically deterministic and arise from lack of knowledge about the plant resulting from modeling assumptions, neglected effects (e.g., unmodeled dynamics), and parametric

uncertainties resulting from inaccurate measurements or operational variability. These analysis methods and tools will be used iteratively with simulation evaluations and experimental testing methods, as described herein, to comprehensively assess nonlinear and adaptive control systems that enable resilience under multiple hazards.

Current research efforts on software verification focus on argument-based safety assurance for highly complex integrated systems of systems; assessment tools for evaluating the safety and coordination of authority and autonomy assignments; methods for ensuring safety-critical properties of distributed systems; and the development of tools and techniques for assessing software-intensive systems in meeting performance safety objectives. Research on software-intensive systems includes the development of methods and tools to detect, diagnose, and predict adverse events due to a software fault or failure once the software has been verified and is in operation. Some recent references on this work include Holloway (2012), Xu et al. (2013), Driscol et al. (2012), Person et al. (2011), and Latorella and Feary (2011).

Research has been initiated on developing methodologies for determining (i.e., quantifying) the predictive capability of the validation process for systems designed to operate under conditions that cannot be fully replicated during evaluations. Predictive capability assessment is an evaluation of the validity and level of confidence that can be placed in the validation process and results under nominal and hazardous conditions (and their associated boundaries). The need for this evaluation arises from the inability to fully evaluate these technologies under actual hazards to be encountered by the fielded system. A detailed disclosure is required of model, simulation, and emulation validity for the off-nominal conditions being considered in the validation, interactions that have been neglected, assumptions that have been made, and uncertainties associated with the models and data. Cross-correlations should be utilized between analytical, simulation, and ground test and flight test results in order to corroborate the results and promote efficiency in covering the very

V

large space of operational and off-nominal and hazardous conditions being evaluated. The level of confidence in the validation process and results must be established for subsystem technologies as well as the fully integrated system. This includes an evaluation of error propagation effects across subsystems and an evaluation of integrated system effectiveness in mitigating hazardous conditions and preventing cascading errors, faults, and failures across subsystems. Metrics for performing this evaluation are also needed.

Vehicle Dynamics Control

Eric Tseng
Ford Motor Company, Dearborn, MI, USA

Abstract

Current prevailing control technology enables vehicle dynamic control through powertrain torque manipulation and individual wheel braking. Longitudinal control can maintain vehicle acceleration/braking capability within the physical limits that the road condition can support, while vehicle lateral control can preserve vehicle steering/handling capability up to the

maximum capacity offered by the road/tire interaction. Since most of these controllers are driver-assist systems, their objective is to retain the vehicle dynamic state in operating regions familiar to drivers. In general, this implies that the controller will keep the tire in its linear region and avoid excessive slipping, skidding, or sliding.

Keywords

Active yaw control; Electronic stability control; Evasive maneuvers; Lateral dynamics; Traction assist; Traction control; Vehicle stability assist

Introduction

Vehicle dynamics control generally refers to the active modification of longitudinal and lateral tire forces and the corresponding dynamics of ground vehicles using sensors and actuators. While it may also include vehicle active or semi-active suspension control (Hrovat 1997), vehicle dynamics control in this entry will focus on traction control – vehicle longitudinal control and electronic stability control – combined vehicle longitudinal and lateral control.

Simply speaking, tire force is generated when there exists a velocity difference between tire tread and the ground, also known as tire slip. As illustrated in Fig. 1, the longitudinal tire force

first grows proportionally with the tire slip, in a so-called linear region, and then saturates as tire slip passes beyond a certain threshold. The figure also shows the coupling effect between longitudinal and lateral tire forces. That is, the available lateral force (as a function of tire slip angle) decreases when the longitudinal tire slip increases, and the available longitudinal force (as a function of tire slip) decreases as the lateral tire slip angle increases. This coupling effect is essential for understanding vehicle dynamics and leads to numerous control applications.

Traction Control

Since vehicle motion relies on the tire/ground interaction, it is important for the purpose of vehicle controllability to maintain tire/road interaction in a linear and predictable way. Anti-lock braking systems (ABS), and traction control (TC) in particular, monitor and control the tire slip so that the longitudinal tire force can best support and balance the corresponding brake torque (during ABS intervention) or driveline torque (during TC intervention) delivered to the wheels. Without the wheel/tire slip control, tire force may saturate, resulting in both the reduction of longitudinal and lateral tire force capacity, with the corresponding reduction in decelerating/accelerating capability, or loss of road grip/lateral tire force capacity.

Vehicle Dynamics Control, Fig. 1 Longitudinal and lateral tire force as a function of tire slip and slip angle
Control Design

The objective of a TC system is to ensure longitudinal tire force capacity while maintaining a good margin on available lateral force road grip (see Fig. 1). Based on the tire force/slip characteristics, this can be achieved by regulating the longitudinal tire slip, roughly defined as the relative velocity between the contact patch of the tire and the road surface. This can be expressed as the difference between the vehicle traveling speed and tire rotational speed, as defined in Eq. 1, according to the Society of Automotive Engineers (SAE), where V is the vehicle speed, ω is the angular speed of the tire, and R is the effective tire rolling radius. The effective rolling radius is defined so that vehicle speed equals the product of R and ω (i.e., $V = R\,\omega$) when there is no torque applied to the wheel and the tire is free rolling.

$$s = \frac{V - R\omega}{V}, \tag{1}$$

At low slip, the longitudinal tire force grows as the slip increases (Carlson and Gerdes 2003), while at high slip it passes its peak and begins to decrease (Deur et al. 2004). High slips occur when wheels are locked during braking or are overspinning during acceleration. A traction control system uses feedback control to regulate wheel/tire slip.

Sensors and Actuators

To regulate driven wheel slips effectively with closed loop control, wheel speed sensors at the non-driven wheels are utilized for vehicle speed estimation (V in Eq. 1). In the case of all-wheel drive or four-wheel drive systems, a longitudinal accelerometer is typically added for the speed estimate. As the amount of desired wheel slip may vary depending on maneuvers, accelerator pedal, steering angle, and yaw rate signals may be used as well. Some systems deploy steering wheel angle and yaw rate sensors for direct signal assessment and signal sharing competency, while others estimate these signals based on the speed difference between left and right wheels, for

subsystem modularity across various vehicle configurations and platforms as well as calibration independency.

Powertrain and brake torque modulation are typically used for actuation to regulate driven wheel slips.

Control System Behavior

Wheel/tire slip targets are typically adjusted based on vehicle driveline configurations as well as vehicle maneuvers. When a vehicle is cornering, a low slip target is generated to assure sufficient margin in lateral tire force capacity. Similarly, rear wheel drive vehicles may warrant a lower slip target than front or all-wheel drive vehicles. When a driver presses hard on the accelerator pedal, the slip target can be raised to accommodate higher acceleration. In addition, the target can be adjusted based on vehicle speed and estimated road available friction, all in an attempt to optimize the longitudinal traction force while keeping sufficient margin on lateral grip (Fodor et al. 1998; Hrovat et al. 2000).

Uniform Friction Surface: (Uniform mu)
Unless equipped with advanced driveline mechanism such as active limited slip differential or torque vectoring differential (Deur 2010), a vehicle is typically equipped with open differential, thus transmitting the powertrain torque evenly to both left and right driven wheels. Since there is no difference between the left and right wheel torque that can be supported by the uniform driving surface, wheel slip regulation can be quite effectively achieved by modulating only the powertrain torque. One successful example of this is Ford's engine-only traction control system, introduced in 2006 on its Fusion and F150 models, which was well received by media experts and customers (Healey 2005).

Nonuniform Friction Surface: (Split mu)
For driving surfaces offering different tire/road characteristics, different wheel torque can be supported on different sides. In this case, a

V

vehicle equipped with an open differential would transmit only the minimum torque (set by the low friction side) to the road. Any additional driveline torque that cannot be supported by the road surfaces results in spinning the wheel on the low friction side. Since open differential transmits equal amount of torque left and right, the additional tire force available on the higher friction side would not be fully utilized with powertrain only actuation. In this case, by applying additional brake torque at the low road friction side, the driveline torque can be balanced at the higher level offered by the high friction side. Care must be taken to avoid aggressive brake application which can cause driveline and/or half shaft oscillations (Fodor et al. 1998; Hrovat et al. 2000).

Control Challenges

Given that road/tire interaction varies with multiple environmental factors, the tire force/slip relationship depicted in Fig. 1 is only a qualitative characterization, and the actual optimal slip for a desired traction force is difficult to accurately establish. While the peak traction force and the corresponding road friction potential (i.e., mu) can be detected once the wheel starts to spin, it is difficult to do so prior to a wheel spin event (Gustafsson 1996).

Since the powertrain actuation is less perceptible yet occasionally sluggish, and the brake application can be fast but intrusive at times, it can be a control challenge to optimize the actuation combination and bandwidth.

If a priori knowledge of friction potential and optimal slip can be learned, detailed powertrain/driveline actuation delay and dynamics can be modeled, and optimal actuation combination and bandwidth can be incorporated; it is conceivable that further improvement in wheel slip and traction control can be achieved, using advanced control approaches such as model predictive control (Borrelli et al. 2006), for example.

Electronic Stability Control

According to the Society of Automotive Engineers (SAE), an electronic stability control system (ESC) is a computer-controlled system that augments vehicle directional stability by applying and adjusting individual wheel braking. It is operational over the full speed range of the vehicle and is capable of monitoring both driver steering input and vehicle yaw rate to limit vehicle understeering and oversteering, as appropriate.

The wide proliferation of ESC in recent years (Van Zanten 2000) across the vehicle fleet has allowed various evaluation studies of its effectiveness in real-world environments. Among them, the United States NHTSA (National Highway Traffic Safety Administration) study (Dang 2004) concluded that ESC reduces fatal single vehicle crashes by 35 %, while single vehicle crashes involving sport utility vehicles (SUVs) are reduced by 67 %. Similar conclusions were arrived in other subsequent studies, including the statement that "Electronic stability control could prevent nearly one-third of all fatal crashes . . . " from the Insurance Institute for Highway Safety organization (IIHS 2006). Many of these effectiveness studies are summarized in a literature review by Ferguson (2007).

Control Design

The objective of an ESC system is to provide vehicle controllability and predictability to assist the driver. This can be achieved by preventing excessive deviations between the intended and actual lateral response of the vehicle, especially during critical maneuvers such as a sudden encounter with a slippery/icy road.

During driving, a driver relies on a mental model of the vehicle's response to his/her steering input developed from previous driving experience. A vehicle model, as described in Eq. 2 and Fig. 2, is often used to describe nominal lateral vehicle behaviors.

**Vehicle Dynamics
Control, Fig. 2** Vehicle
cornering model
$$m\dot{v}_y = -mV\dot{\psi} + F_{yf}(v_y, V, \delta, F_{xf})$$
$$+ F_{yr}(v_y, V, \delta, F_{xr})$$
$$I\ddot{\psi} = 2aF_{yf} - 2bF_{yr}$$
$$+ c(-F_{xf,l} + F_{xf,r} - F_{xr,l} + F_{xr,r}) \quad (2)$$

where m is the vehicle mass; V and V_y are vehicle longitudinal and lateral velocity, correspondingly; $\dot{\psi}$ is vehicle yaw rate; and δ is the steering angle. Parameters a and b are the distance between vehicle center of gravity to front and rear axle; c is the half track width. F_x and F_y denote the longitudinal and lateral/cornering tire force, with subscript indicating longitudinal (x) or lateral (y) direction, as well as the specific corner of the vehicle (front, rear, left, and right).

Note that the corresponding longitudinal dynamics can be described as

$$m\dot{V} = mv_y\dot{\psi} + F_{xf,l} + F_{xr,l} + F_{xf,r} + F_{xr,r} \quad (3)$$

As the available road friction is not always known, a nominal vehicle lateral response derived from a hi-mu surface may not be feasible and may not best represent a driver's intent. To modify the feedback to best adapt to the road condition, ESC would do one or more of the following: Adjust the driver intended yaw rate according to detected lateral acceleration capability (Tseng et al. 1999), balance between yaw

rate and lateral acceleration error when both are compared to a nominal vehicle model (Manning and Crolla 2007), or balance between yaw rate error and detected excessive sideslip angle (Di Cairano et al. 2013).

Sensors and Actuators

In order to effectively provide vehicle controllability through an embedded controller, ESC systems are equipped with a steering angle sensor, wheel speed sensors, a yaw rate sensor, and a lateral accelerometer. Additional sensors such as a longitudinal accelerometer and a roll rate sensor may be installed to better observe the vehicle dynamic states and provide improved fidelity for estimated vehicle behaviors. The actuators of an ESC system are the individual wheel brakes and powertrain torque.

Control System Behavior

A vehicle can exhibit understeering and/or oversteering behaviors during aggressive lateral maneuvers. Figure 3 illustrates how a vehicle equipped with ESC may provide better controllability.

Understeering – When a vehicle does not turn in as much as desired by the driver (see

Vehicle Dynamics Control, Fig. 3 Vehicle going through a hairpin turn

upper Fig. 3). In this case, the vehicle yaw rate, an ESC measured/monitored signal, would be less than the driver desired value. For example, a vehicle on ice may experience extreme understeering that keeps the vehicle moving straight even when the steering wheel is turned. In this case, ESC applies corrective yaw moment to increase the yaw rate through individual wheel braking. Most of the longitudinal braking force is applied on rear axle inside wheel in the attempt to increase the lateral force capacity on the front axle while decreasing the lateral force capacity on the rear axle. As such, the vehicle experiences not only the yaw moment correction but also the reduction of understeering tendency with ESC brake application.

Oversteering – When a vehicle turns too much, i.e., yaws with a smaller turning radius than the one needed to negotiate the road (see lower Fig. 3). In this case, the vehicle yaw rate would be larger than the driver desires. The vehicle tends to build up a large sideslip angle, resulting in a spinout due to the saturation of rear tire force. In this case, ESC applies corrective yaw moment to decrease the size of yaw rate through individual wheel braking. The longitudinal braking force is applied mostly on the front axle outside wheel to preserve the lateral force capacity on the rear axle and decrease the lateral force capacity on the front axle. As such, the vehicle experiences not only the yaw moment correction but also the reduction of oversteering tendency with ESC brake application.

Evasive Maneuver – During an evasive maneuver, such as an aggressive double lane change, the vehicle may first turn in one direction, followed by an oversteer in the other direction. Due to delay and lag of actuator response in practice, feedforward control is typically used to ensure brake

application would generate corrective yaw moment in the appropriate direction. Further improvement could be possible by using road/traffic preview along with (semi)autonomous intervention based on advanced optimal control such as model predictive control (Falcone et al. 2008), for example.

Skidding and Oversteering – When both front and rear tires experience large tire slip angle, both tire forces are saturated. In this case, the vehicle is operating in a region where the rear tire slip angle can grow rapidly. Unless the front steering is delicately and quickly balanced, the excessive rear tire slip angle could cause the vehicle to spin out. In this case, in addition to applying corrective yaw moment similar to the above oversteering case, ESC may command light braking on all four wheels in an attempt to further slow down the vehicle.

Rollover Mitigation – An ESC system may be extended to further provide a more controllable vehicle behavior and mitigate rollover risks in evasive maneuvers that demand a large and sudden lateral force. For example, Roll Stability Control ^{TM} system introduced at Ford in 2003 monitors vehicle roll behavior in addition to vehicle yaw behavior to assist the driver (Lu et al. 2007).

Control Challenges

In order to best provide the assistance to drivers' desire, it is important to assess the vehicle dynamic state and driver intention with high fidelity. This can be challenging in the presence of various factors that directly influence the vehicle behavior or sensor readings but are not or cannot be directly measured. For example, the road bank angle information is typically unavailable, but it has a direct influence on the lateral accelerometer measurement and could be misinterpreted as a discrepancy between vehicle yaw rate and lateral force (Tseng 2001; Tseng et al. 2007). And despite its criticality in vehicle dynamics control,

the available road surface friction capacity and the vehicle sideslip angle typically cannot be measured (Tseng 2002, Ryu 2002, Ahn et al. 2013). The driver's intent is prescribed by a mental model in the computer, but we cannot directly read the driver's mind. In addition, the controller should detect when a sensor is misbehaving and giving out false or biased readings (Xu and Tseng 2007). While advanced observers have been developed to address these challenges, it is foreseeable that optimization in these areas could further improve the observer fidelity and overall ESC performance.

Abstract

Even since the pioneering work of Levine and Athans and Melzer and Kuo, control of vehicular formations has been a topic of active research. In spite of its apparent simplicity, this problem poses significant engineering challenges, and it has often inspired theoretical developments. In this article, we view vehicular formations as a particular instance of dynamical systems over networks and summarize fundamental performance limitations arising from the use of local feedback in formations subject to stochastic disturbances. In topology of regular lattices, it is impossible to have coherent large formations, which behave like rigid lattices, in one and two spatial dimensions; yet this is achievable in 3D. This is a consequence of the fact that, in 1D and 2D, local feedback laws with relative position measurements are ineffective in guarding against disturbances with slow temporal variations and large spatial wavelength.

Keywords

Introduction

Control of vehicular strings has been an active area of research for almost five decades (Levine and Athans 1966; Lin et al. 2012; Melzer and Kuo 1971a, b; Middleton and Braslavsky 2010;

Seiler et al. 2004; Swaroop and Hedrick 1996, 1999; Varaiya 1993). This problem represents a special instance of more general vehicular formation problems which are encountered in the control of unmanned aerial vehicles, satellite formations, and groups of autonomous robots (Bullo et al. 2009; Mesbahi and Egerstedt 2010). Even for the simplest control objective, in which it is desired to maintain a constant cruising velocity and a constant distance between the neighboring vehicles, it has been long recognized that limited information exchange between the vehicles imposes fundamental performance limitations for control design. In particular, look-ahead strategies that rely only on relative spacing information with respect to the preceding vehicle suffer from *string instability*. This phenomenon is characterized by unfavorable amplification of disturbances downstream the vehicular string (Middleton and Braslavsky 2010; Seiler et al. 2004; Swaroop and Hedrick 1996, 1999). In order to avoid this unfavorable spatial application, it is typically required to broadcast the state of the leader to the rest of the formation.

While a precise characterization of fundamental performance limitations in the control of vehicular formations is still an open question, in this article we review recent progress in this area. We begin by highlighting performance limits that arise even in optimally controlled vehicular strings. The LQR problem for vehicular strings was originally formulated in pioneering papers by Levine and Athans (1966) and Melzer and Kuo (1971a, b). These formulations were revisited in Jovanović and Bamieh (2005) where it was shown that the time constant of the optimally controlled closed-loop system increases linearly with the number of vehicles. This reference also employed spatially invariant theory (Bamieh et al. 2002) to demonstrate the lack of exponential stability in the limit of an infinite number of vehicles and to explain the arbitrarily slowing rate of convergence observed in numerical studies of finite strings of increasing sizes. We then summarize a recent result that viewed vehicular strings as the 1D version of vehicular formations on regular lattices in arbitrary spatial dimensions and established fundamental

performance limitations of spatially invariant localized feedback strategies with relative position measurements (Bamieh et al. 2012). It was shown that it is impossible to achieve robustness to stochastic disturbances with only localized feedback in 1D and 2D; yet this can be achieved in 3D. This is a consequence of the fact that, in 1D and 2D, local feedback laws are ineffective in guarding against disturbances with slow temporal variations and large spatial wavelength. An "accordion" type of motion experienced by these spatiotemporal modes compromises formation throughput, and it may occur even in formations that are string stable. Since the phenomenon that we describe also occurs in distributed averaging algorithms, global mean first passage time of random walks, effective resistance in electrical networks, and statistical mechanics of harmonic solids, it is relevant for a broad class of networked dynamical systems.

Optimal Control of Vehicular Strings

We next summarize a linear quadratic regulator problem for vehicular strings (Levine and Athans 1966; Melzer and Kuo 1971a, b) and demonstrate that strategies that penalize only relative position errors between neighboring vehicles yield nonuniform rates of convergence towards the desired formation (Jovanović and Bamieh 2005). In particular, the time constant of the optimally controlled closed-loop system increases linearly with the number of vehicles, and the formation loses exponential stability in the limit of infinite vehicular strings.
Optimal Control of Finite Strings

A string consisting of M identical unit mass vehicles is shown in Fig. 1a. Each vehicle is modeled as a point mass that obeys the double-integrator dynamics:

$$\ddot{x}_n = u_n, \quad n \in \{1, \dots, M\} \tag{1}$$
Vehicular Chains, Fig. 1 Finite and infinite strings of vehicles

Vehicular Chains, Fig. 2 Finite string with fictitious lead and follow vehicles

where x_n is the position of the nth vehicle and u_n is the control applied on the nth vehicle. A control objective is to provide the desired constant cruising velocity $\bar{v}$ and to keep the constant distance δ between the neighboring vehicles. By introducing the absolute position and velocity error variables

$$p_n(t) := x_n(t) - \bar{v}t + n\delta$$
$$v_n(t) := \dot{x}_n(t) - \bar{v}, \qquad n \in \{1, \dots, M\}$$

system (1) can be brought into the state-space form (Melzer and Kuo 1971a, b):

$$\begin{bmatrix} \dot{p} \\ \dot{v} \end{bmatrix} = \begin{bmatrix} 0 & I \\ 0 & 0 \end{bmatrix} \begin{bmatrix} p \\ v \end{bmatrix} + \begin{bmatrix} 0 \\ I \end{bmatrix} u =: A\psi + Bu \tag{2}$$

where $p := [p_1 \cdots p_M]^T$, $v := [v_1 \cdots v_M]^T$, and $u := [u_1 \cdots u_M]^T$.

Following Melzer and Kuo (1971a, b), fictitious lead and follow vehicles, respectively, indexed by 0 and $M + 1$, are added to the formation; see Fig. 2. These two vehicles are constrained to move at the desired velocity $\bar{v}$, and the relative distance between them is assumed to be equal to $(M + 1)\delta$ for all times. A quadratic performance index that penalizes control effort, relative position, and absolute velocity error variables is associated with system (2):

$$J = \frac{1}{2} \int_0^\infty \left(\sum_{n=1}^{M+1} q_p (p_n(t) - p_{n-1}(t))^2 \right.$$
$$\left. + \sum_{n=1}^M (q_v v_n^2(t) + r\, u_n^2(t)) \right) dt$$
$$= \frac{1}{2} \int_0^\infty (\psi^*(t) Q \psi(t) + u^*(t) R u(t)) dt. \tag{3}$$

The control problem (2) and (3) is in the standard LQR form with the state and control weights:

$$Q := \begin{bmatrix} Q_p & 0 \\ 0 & q_v I \end{bmatrix}, \quad Q_p := q_p T_M, \quad R := rI.$$

Here, T_M is an $M \times M$ symmetric Toeplitz matrix with the first row given by $[\, 2 -1\, 0 \cdots 0\,] \in \mathrm{R}^M$.

We next briefly summarize the explicit solution to the LQR problem (2) and (3) and refer the reader to Jovanović and Bamieh (2005) for additional details. By performing a spectral decomposition of the Toeplitz matrix T_M,

$$T_M = U\Lambda_T U^*, \quad UU^* = U^*U = I$$
$$\Lambda_T = \mathrm{diag}\{\lambda_1(T_M), \dots, \lambda_M(T_M)\}$$
$$\lambda_n(T_M) = 2\left(1 - \cos \frac{n\pi}{M+1}\right), \quad n \in \{1, \dots, M\} \tag{4}$$

the solution to the LQR algebraic Riccati equation can be represented as

$$P := \begin{bmatrix} P_1 & P_0^* \\ P_0 & P_2 \end{bmatrix}, P_0 = U\Lambda_0 U^*, P_2 = U\Lambda_2 U^*,$$
$$P_1 = U\Lambda_1 U^*. \tag{5}$$

Here,

$$\Lambda_0 = \sqrt{rq_p}\, \Lambda_T^{1/2}$$
$$\Lambda_2 = \sqrt{r} \left(2\sqrt{rq_p}\, \Lambda_T^{1/2} + q_v I\right)^{1/2}$$
$$\Lambda_1 = \sqrt{q_p}\, \Lambda_T^{1/2} \left(2\sqrt{rq_p}\, \Lambda_T^{1/2} + q_v I\right)^{1/2}$$

and the eigenvalues of the closed-loop A-matrix are determined by the solutions to the following system of the uncoupled quadratic equations:

$$
\begin{aligned}
s_n^2 + b_n s_n + c_n &= 0, \quad n \in \{1, \ldots, M\} \\
c_n &:= \left(\lambda_n(T_M) q_p / r\right)^{1/2} \\
b_n &:= \left(2c_n + q_v / r\right)^{1/2}.
\end{aligned}
\tag{6}
$$

From the above expression, it can be shown that in large-scale formations, the least-stable eigenvalue of the closed-loop system approaches the imaginary axis at the rate that is inversely proportional to the number of vehicles. As can be seen from the PBH detectability test, this is because the pair (Q, A) gets closer to losing its detectability as the number of vehicles increases. This clearly indicates that the resulting optimal control strategy leads to closed-loop systems with arbitrarily slow decay rates as the number of vehicles increases. As summarized in section "Optimal Control of Infinite Strings," the absence of a uniform rate of convergence for a finite number of vehicles manifests itself as the absence of exponential stability in the limit of infinite vehicular strings.

Optimal Control of Infinite Strings

The LQR problem for a system of identical unit mass vehicles in an infinite string (see Fig. 1b) was originally studied in Melzer and Kuo (1971a). As summarized below, using the theory for spatially invariant linear systems (Bamieh et al. 2002), it was shown in Jovanović and Bamieh (2005) that the resulting LQR controller does not provide exponential stability of the closed-loop system due to the lack of detectability of the pair (Q, A).

The infinite dimensional equivalent of (2) is given by

$$
\begin{bmatrix} \dot{p}_n \\ \dot{v}_n \end{bmatrix} = \begin{bmatrix} 0 & I \\ 0 & 0 \end{bmatrix} \begin{bmatrix} p_n \\ v_n \end{bmatrix} + \begin{bmatrix} 0 \\ I \end{bmatrix}
$$

$$
u_n =: A_n \psi_n + B_n u_n, \quad n \in \mathbb{Z} \tag{7}
$$

$$
J = \frac{1}{2} \int_0^\infty \sum_{n \in \mathbb{Z}} \left(q_p (p_n(t) - p_{n-1}(t))^2 \right.
$$

$$
\left. + q_v v_n^2(t) + r\, u_n^2(t) \right) dt \tag{8}
$$
Vehicular Chains, Fig. 3 The spectra of the closed-loop generators in LQR-controlled finite (*symbols*) and infinite (*solid line*) strings of vehicles with $M = 50$ and $q_p = q_v = r = 1$. The closed-loop eigenvalues of the finite string are points in the spectrum of the closed-loop infinite string. As the number of vehicles increases, the number of eigenvalues that accumulate in the vicinity of the stability boundary gets larger and larger

with q_p, q_v, and r being positive design parameters. Spatial invariance over a discrete spatial lattice Z can be used to establish that the solution to the LQR problem does not provide an exponentially stabilizing feedback for system (7). In particular, the spectrum of the closed-loop generator in an LQR-controlled spatially invariant string of vehicles (7) with performance index (8) is given by the solutions to the following θ-parameterized quadratic equation:

$$
\begin{aligned}
s_\theta^2 + b_\theta s_\theta + c_\theta &= 0, \\
c_\theta &:= \left(2(q_p / r)(1 - \cos \theta)\right)^{1/2} \\
b_\theta &:= \left(2c_\theta + q_v / r\right)^{1/2}
\end{aligned}
\tag{9}
$$

where $\theta \in [0, 2\pi)$ denotes the spatial wave number. By comparing (4), (6) and (9), we see that the closed-loop eigenvalues of the finite string are points in the spectrum of the closed-loop infinite string. Furthermore, from these equations it follows that as the size of the finite string increases, this set of points becomes dense in the spectrum of the infinite string closed-loop A-operator. The spectrum of the closed-loop generator, shown in Fig. 3 for $q_p = q_v = r = 1$, illustrates the absence of exponential stability.

Coherence in Large-Scale Formations

Fundamental performance limitations arising from the use of local feedback in networks subject to stochastic disturbances were recently examined in Bamieh et al. (2012). For consensus and vehicular formation control problems in topology of regular lattices, it was shown that it is impossible to guarantee robustness to stochastic exogenous disturbances in one and two spatial dimensions. Yet it was proved that this is achievable in 3D. This phenomenon is a consequence of the fact that, in 1D and 2D, local feedback laws are ineffective in guarding against disturbances with large spatial wavelength, and it has also been observed in global mean first passage time of random walks, effective resistance in electrical networks, and statistical mechanics of harmonic solids. We next briefly summarize the implications of these results for the control of vehicular formations and refer the reader to Bamieh et al. (2012) for details.

Stochastically Forced Vehicular Formations with Local Feedback

Let us consider $M := N^d$ identical vehicles arranged in a d-dimensional torus, Z_N^d, with the double integrator dynamics:

$$\ddot{x}_n = u_n + w_n \qquad (10)$$

where $n := (n_1, \ldots, n_d)$ is a multi-index with each $n_i \in Z_N := \{0, \ldots, N-1\}$, u is the control input, and w is a mutually uncorrelated white stochastic forcing. Each position vector x_n is a d-dimensional vector with components $x_n := \begin{bmatrix} x_n^1 \cdots x_n^d \end{bmatrix}^T$. The control objective is to have the nth vehicle follow the absolute desired trajectory $\bar{x}_n$:

$$\bar{x}_n := \bar{v}t + n\delta \Leftrightarrow \begin{bmatrix} \bar{x}_n^1 \\ \vdots \\ \bar{x}_n^d \end{bmatrix} := \begin{bmatrix} \bar{v}^1 \\ \vdots \\ \bar{v}^d \end{bmatrix} t + \begin{bmatrix} n_1 \\ \vdots \\ n_d \end{bmatrix} \delta.$$

In other words, it is desired that all vehicles move with constant heading velocity $\bar{v}$ while

maintaining their respective position in a Z_N^d grid with spacing of δ in each dimension.

By introducing the position and velocity deviations from the desired trajectory,

$$p_n := x_n - \bar{x}_n, \quad v_n := \dot{x}_n - \bar{v}$$

and by confining our attention to static-feedback policies,

$$u(t) = -\begin{bmatrix} K_p & K_v \end{bmatrix} \begin{bmatrix} p(t) \\ v(t) \end{bmatrix} \qquad (11)$$

equations of motion for the controlled system (10) can be brought into the state-space form

$$\begin{bmatrix} \dot{p} \\ \dot{v} \end{bmatrix} = \begin{bmatrix} 0 & I \\ -K_p & -K_v \end{bmatrix} \begin{bmatrix} p \\ v \end{bmatrix} + \begin{bmatrix} 0 \\ I \end{bmatrix}$$
$$w \quad =: A\psi + Bw \qquad (12)$$
$$z \quad = C\psi.$$

Here, p and v are the position and velocity vectors of all vehicles, z is the performance output, and w is the forcing vector.

An Example

In one-dimensional formations with nearest neighbor relative position and velocity measurements, the control acting on the nth vehicle is given by

$$\begin{aligned} u_n(t) = &-k_p^-(p_n(t) - p_{n-1}(t)) \\ &-k_p^+(p_n(t) - p_{n+1}(t)) \\ &-k_v^-(v_n(t) - v_{n-1}(t)) \\ &-k_v^+(v_n(t) - v_{n+1}(t)) \end{aligned} \qquad (13)$$

where $k_p^\pm$ and $k_v^\pm$ are positive design parameters. For a system that evolves over a 1D lattice, the feedback gain matrices K_p and K_v are tridiagonal Toeplitz matrices implying that the closed-loop systems have been effectively converted into a mass-spring-damper system shown in Fig. 4. Figure 5 shows the results of a stochastic simulation for the closed-loop system (12) and (13) with 100 vehicles with desired inter-vehicular spacing $\delta = 20$ and $k_p^\pm = k_v^\pm = 1$. These plots indicate the lack of formation coherence. This is only discernible when one "zooms out" to view
Vehicular Chains, Fig. 4 Finite string of vehicles with a nearest neighbor relative position and velocity feedback
Vehicular Chains, Fig. 5 Position trajectories of a stochastically forced formation with 100 vehicles controlled with nearest neighbor strategy (13). *Left plot* demonstrates accordion-like motion of the entire formation; *right plot* shows that vehicle-to-vehicle distances are relatively well regulated

the entire formation. The length of the formation fluctuates stochastically, but with a distinct slow temporal and long spatial wavelength signature. In contrast, the zoomed-in view in Fig. 5 shows a relatively well-regulated vehicle-to-vehicle spacing. In general, small-scale (both temporally and spatially) disturbances are well regulated, while large-scale disturbances are not. This indicates that a local feedback strategy (13) cannot regulate against large-scale disturbances.

(A3) Reflection symmetry. The interactions between vehicles exhibit mirror symmetry.
(A4) Coordinate decoupling. For $d \geq 2$, control in each coordinate direction depends only on measurements of position and velocity error vector components in that coordinate.

While assumptions **(A3)** and **(A4)** were made to simplify calculations, assumptions **(A1)** and **(A2)** were essential for the developments in Bamieh et al. (2012).

Structural Assumptions
We now list the assumptions on the operators K_p, K_v, and C in (12) under which asymptotic scaling trends summarized in section "Scaling of Variance per Vehicle with System Size" are obtained.
(A1) Spatial invariance. Operators K_p, K_v, and C in (12) are spatially invariant with respect to Z_N^d.
(A2) Spatial localization. The feedback (11) uses only local information from a neighborhood of width $2q$, where q is independent of N.

Performance Measures
We next examine the dependence of the steady-state variance of stochastically forced system (12) on the number of vehicles. In the presence of relative position or velocity measurements, the matrix A in (12) is not necessarily Hurwitz, and the state ψ may not have finite steady-state variance. However, for connected networks, the performance output z that does not penalize the motion of the mean will have finite steady-state variance; this is because the modes of A at the origin will be unobservable from z. The steady-state variance of z,

$$V := \sum_{n \in Z_N^d} \lim_{t \to \infty} \mathcal{E}\left(z_n^T(t) z_n(t)\right) \qquad (14)$$

is quantified by the square of the H_2 norm of the system (12) from w to z, and it can be determined from the solution of the algebraic Lyapunov equation.

We next summarize two different performance measures for stochastically forced vehicular formations.

(P1) Local error. This is a measure of the difference of neighboring vehicles positions from the desired spacing. In 1D, the performance output of the nth vehicle is given by

$$z_n := p_n - p_{n-1}.$$

In d-dimensions, the performance output vector contains as its components the local error in each respective dimension. Since this output involves quantities local to any vehicle within a formation, the corresponding steady-state variance is referred to as a *microscopic performance measure*, V_{micro}.

(P2) Deviation from average. This is a measure of the deviation of each vehicle's position error from the average of the overall position error.

$$z_n := p_n - \frac{1}{M} \sum_{j \in Z_N^d} p_j. \qquad (15)$$

Since this output determines deviation from average, and thereby quantities that are far apart in

the network, the corresponding steady-state variance is referred to as a *macroscopic performance measure*, V_{macro}.

Scaling of Variance per Vehicle with System Size

We next summarize asymptotic bounds for both microscopic and macroscopic performance measures derived in Bamieh et al. (2012). The upper bounds result from simple feedback laws similar to the one given in (13). In the situations where either absolute position or velocity measurement are available, additional terms proportional to p_n and v_n will appear in (13). The lower bounds have been obtained for any linear static feedback control policy satisfying the structural assumptions **(A1)–(A4)** and the following constraint on control variance at each vehicle:

$$\mathcal{E}\left(u_n^T u_n\right) \leq U_{\text{max}}. \qquad (16)$$

Under this constraint, the equivalence between scaling trends of lower and upper bounds can be established. As illustrated in Table 1, the dependence of the asymptotic bounds on the number of vehicles is strongly influenced by the underlying spatial dimension d.

Since the macroscopic performance measure captures how well the formation regulates against large-scale disturbances, the scaling results presented in Table 1 demonstrate that local feedback with relative position measurements is unable to regulate against these large-scale

Vehicular Chains, Table 1 Asymptotic scalings of microscopic and macroscopic performance measures in terms of the total number of vehicles $M = N^d$, the spatial dimensions d, and the control effort per vehicle U_{max}. Quantities listed are up to a multiplicative factor that is independent of M or U_{max}:

Feedback type	V_{micro}/M	V_{macro}/M
Absolute position Absolute velocity	$\frac{1}{U_{\text{max}}}$	$\frac{1}{U_{\text{max}}}$
Relative position Absolute velocity	$\frac{1}{U_{\text{max}}}$	$\frac{1}{U_{\text{max}}} \begin{cases} M & d=1 \\ \log(M) & d=2 \\ 1 & d \geq 3 \end{cases}$
Relative position Relative velocity	$\frac{1}{U_{\text{max}}^2} \begin{cases} M & d=1 \\ \log(M) & d=2 \\ 1 & d \geq 3 \end{cases}$	$\frac{1}{U_{\text{max}}^2} \begin{cases} M^3 & d=1 \\ M & d=2 \\ M^{1/3} & d=3 \\ \log(M) & d=4 \\ 1 & d \geq 5 \end{cases}$

disturbances in 1D. To the contrary, in higher spatial dimensions, local feedback can regulate against large-scale disturbances and provide formation coherence. As shown in Table 1, the "critical dimension" needed to achieve network coherence depends on the type of feedback strategy: dimension 3 for relative position and absolute velocity feedback and dimension 5 for relative position and velocity feedback.

Summary and Future Directions

For stochastically forced vehicular formations in topology of regular lattices, we have summarized fundamental performance limitations resulting from the use of local feedback. Even for formations that are string stable, local feedback is not capable of guarding against slowly varying disturbances with long spatial wavelength in 1D and 2D. The observed phenomenon also arises in distributed averaging and estimation algorithms, global mean first passage time of random walks, effective resistance in electrical networks, and statistical mechanics of harmonic solids. Since performance measures that we used to quantify robustness to disturbances are easily extensible to networks with arbitrary topology and more complex node dynamics, they can be used to evaluate performance of a broad class of networked dynamical systems in future studies.

Vibration Control System Design for Buildings

Hidekazu Nishimura
Graduate School of System Design and Management, Keio University, Yokohama, Japan

V

Abstract

This entry reviews vibration control system design of buildings in terms of energy dissipation and seismic isolation including full active control devices and semi-active or passive

devices. Vibration control of buildings subjected to dynamic loadings such as large earthquakes, strong winds, or heavy traffic is one of the most important factors to take into consideration to secure the users. Since energy dissipation is the key technology in vibration control, many kinds of devices have been developed for structural mitigation. Seismic retrofit of buildings is very important because long-period earthquakes occur at considerable distances from the seismic center. Here, we introduce the application of specific devices to the vibration control system design of real buildings, especially in Japan, where there are many earthquakes.

Keywords

Active control; Base isolation; Energy dissipation; Seismic response control; Seismic retrofit; Semi-active control; Vibration control

Introduction

Vibration control of buildings subjected to dynamic loadings such as large earthquakes, strong winds, or heavy traffic is one of the most important factors to consider for the safety of building occupants. Energy dissipation is the key technology in vibration control, and many kinds of devices have been developed for structural mitigation (Soong and Spencer 2002; Spencer and Nagarajaiah 2003). In Japan, the 2011 earthquake occurred on the Pacific coast of Tohoku, prolonged for an extended period to the Tokyo area 400 km away from the seismic center, and caused fatal damages to the buildings of the surrounding areas.

Therefore, seismic retrofitting of buildings is very important in Japan because long-period earthquakes occur at sites far away from their seismic center as well. In particular, old super-high-rise buildings are concentrated in the central ward of Tokyo, Shinjuku, and they have been built on the basis of the theory of flexible structures. During a long-period earthquake, super-high-rise buildings have very

large displacement (about 0.5 m) because of resonance vibration and may need a few minutes to dissipate the structural vibrations. These buildings need to be retrofitted by adding some energy dissipating devices, such as active mass dampers (AMDs), tuned mass dampers, rotating inertial mass dampers, and passive/semi-active base isolation devices.

This entry reviews a vibration control system design of buildings in terms of energy dissipation and seismic isolation including full active control devices and semi-active or passive devices. We introduce the application of specific devices to the vibration control system design of real buildings.

Active Mass Damper

Active, semi-active, or passive mass damper systems have been installed in a large number of high-rise buildings as shown in Fig. 1 (Soong and Spencer 2002; Spencer and Nagarajaiah 2003). Although active mass dampers have historically
Vibration Control System Design for Buildings, Fig. 1
Active, semi-active, or passive mass damper system installed in an n-storied building subjected to wind force and ground motion

used ball-screw-type actuators, the IHI Corporation has now developed AMDs driven by a linear motor, making the production of a long stroke type easier than that in the case of the ball-screw-type actuator (Koike et al. 2011). Other advantages of using a linear actuator are lesser noise and vibration, lightweight, and compactness. Thanks to these advantages, it is expected that linear motor type AMDs will be installed in existing buildings as seismic retrofitting devices. To avoid reaching the stroke length limit of the actuator because of a large earthquake, a displacement control of the mass is applied. A phase lead compensation in response to the displacement signal is used to preview the mass stroke.

The two AMDs have been installed in the Docomo Tohoku building of Japan in the same direction to improve by 9.5 % the damping ratio of the 1st mode of the translational vibration. The weight of the mass is 20,000 kg, and the total weight of the device is about 25,000 kg. The control experiment was performed by exciting the building with AMDs, and a damping ratio of 11 % was obtained by activating the vibration control with AMDs.

Seismic Retrofitting

Shimizu Corporation modified the super-high-rise building (height = 100 m) in the Shibaura ward of Tokyo, Japan, by installing rotational inertia mass dampers. The rotational inertia mass damper has a mechanism consisting of a ball screw and a rotational inertia mass, with which the relative translational displacement between stories can be changed to rotational motion of the damper to efficiently increase the dissipation of the kinetic energy.

Although in the previous seismic retrofitting many dampers have been distributed in each floor as shown in Fig. 2a, Shimizu Corporation concentrated the rotational inertia mass dampers on the lower floors of the building (e.g., 1–7) as shown in Fig. 2b. The seismic response against the 2011 Tohoku earthquake would now be reduced by about 35 % not only for the maximum displacement but also for the maximum acceleration of the top floor. Moreover, the duration time would become 220 s instead of 400 s. The method of retrofitting super-high-rise buildings is very unique because the lower floors behave as isolation layers of the base isolation system. Although the displacement of the lower floors becomes

Vibration Control System Design for Buildings, Fig. 2 Seismic retrofitting. (**a**) Distributed energy dissipation device. (**b**) Energy dissipation device concentrated in lower floors

Distributed energy dissipation device

Energy dissipation device concentrated in lower floors
slightly larger than that before the retrofit, the whole building has a good seismic response performance.

Semi-active Base Isolation

The semi-active base isolation system as shown in Fig. 3 has been mounted in a building for the first time in 2000. The building is located on the Yagami campus of the Keio University in Yokohama, Japan, and the base isolation system in two directions consists of eight semi-active hydraulic dampers that can change the damping coefficient in four steps using a controllable orifice. The maximum damping force is 640 kN, while the switching law of damping coefficients is based on the optimal bilinear control theory. The damper is modeled on the lines of the Maxwell model, where a spring and a damper are connected in series, and the objective function on the kinetic energy of the building and the constraint function of the squared damping force are adopted (Yoshida and Fujio 2000).

Vibration Control System Design for Buildings, Fig. 3 Semi-active base isolation system

In 2008, another type of semi-active base isolation system has been installed by Collaboration Complex in the Hiyoshi campus of the Keio University in Yokohama, Japan. The system consists of eight semi-active dampers along with eight conventional hydraulic fluid dampers in each direction of the X–Y axes. While the maximum force of the semi-active damper and the conventional hydraulic fluid damper is about 1,000 kN, the semi-active damper can change the damping coefficient in two steps, high side, 3.68 MNs/m and low side, 1.23 MNs/m. When an earthquake manifests, the high damping coefficient in normal status is switched to the low side. This switch enables the suppression of the acceleration response of the building at the early stages of the earthquake. After the early stage, according to the acceleration response filtered on the isolation layer, the low damping coefficient should be switched to the high side again to avoid the collision of the building with the foundations.

Magneto-rheological (MR) fluid dampers have been studied by many researchers, and in 2001, two 300 kN MR fluid dampers have been installed in Nihon-Kagaku-Miraikan, the Tokyo National Museum of Emerging Science and Innovation. Similarly in 2003, 400 kN MR fluid dampers have been installed in a residential building in Japan (Fujitani et al. 2003).

Although MR fluid dampers have been controlled by various laws (Jansen and Dyke 2000), a gain-scheduled control method was introduced to control the electric current generated by the electromagnet of the MR damper (Nishimura et al. 2002). A system controlled by a damping force is a bilinear control system, where the control input depends not only on the relative velocity but also on the damping coefficient. A virtual semi-active damper model was proposed that is capable of changing the damping coefficient with the valve open ratio, which is assumed to be governed by the input to the dynamics of 2nd-order system. In this device, the optimized variable damping coefficient is determined by the input. Moreover, the valve opening ratio is limited to certain values to constrain the damping force to the maximum value. However, the controllability of the bilinear control system using the variable damping force

depends on the relative velocity of the damper. If the relative velocity equals zero, then the system is uncontrollable. Thus, the systems relative to the positive and the negative sides of the relative velocity are separated. Furthermore, the current–force relationship of the MR damper is considered.

The control method using an MR damper was verified on a 9 m high building-like structure. The structure had four degrees of freedom and a total weight of about 33,000 kg. The MR damper has a maximum force of about 40 kN and its current–force relationship is nonlinear (Watakabe et al. 2008). The experimental results demonstrated a good seismic isolation performance in comparison with the skyhook control. The gain-scheduled control proposed gently varied the damping force according to the input current.

Full Active Base Isolation

Full active base isolation systems have been studied by many researchers (Nishimura and Kojima 1999) who evidenced that they are affected by the saturation of the force generated by the actuator following a large earthquake. The seismic isolation performance should be held even though the force saturation occurred. To control the vibrations, it was proposed to use a hyperbolic function for representing the saturation to smooth the input force (Itagaki and Nishimura 2005).

In 2010, the Obayashi Corporation implemented the active base isolation system in real buildings (Endo et al. 2011). Two hydraulic actuators are connected to the building through a spring in each direction of the X–Y axes to avoid the transmission of the high-frequency vibration from the actuator to the building. The control system is based on the displacement control of the hydraulic actuator and achieves absolute seismic control. The control force is necessary to eliminate the spring and damper forces in the isolation layer, and the skyhook damper force is added to the control force for the stabilization of the whole system.

A trigger mechanism using a friction damper is equipped with serial hydraulic actuators and can avoid the transmission of the excess input force from the actuator to the building. If the excess input force is generated from the actuator in fail, the friction damper can absorb a force of about 1,000 kN so as not to damage the building and the actuator itself. The maximum force of the hydraulic actuator is 1,100 kN, the maximum displacement of the hydraulic actuator is 200 mm, the maximum displacement of the lead–rubber bearing is 500 mm, the maximum displacement of the trigger mechanism with the friction damper is 750 mm, the spring constant of the connected spring is 16,300 kN/mm, and the maximum stroke is 58 mm. Compared to passive isolation, simulations demonstrated that the base isolation system performed well, especially during earthquakes with maximum acceleration less than $200 \, cm/s^2$.

Summary and Future Directions

Seismic retrofitting may become increasingly important for protecting buildings from large and long-period earthquakes. The optimization of the structural mitigation as a whole system must be the objective of future studies aiming to achieve an effective energy dissipation and seismic isolation of buildings. Energy harvesting from vibration control or three-dimensional isolation devices will draw attention in the near future.

Walking Robots

Ambarish Goswami
Honda Research Institute, Mountain View,
CA, USA

Abstract

This article presents an overview of mobile "walking" robots that use their legs to move from one place to another. Walking robots represent a fascinating class of machines which holds the potential for breakthrough applications and inspires multidisciplinary research with rich scientific content. The key feature that separates walking robots from all other classes of mobile robots is their ability to explore unprepared surfaces using discrete footholds. In this respect, these robots are truly the machine counterparts of biological land animals.

Keywords

Balance; Fall; Gait; Humanoid robots

Introduction

The adventure of modern robotics is generally considered to have started from the middle of the twentieth century (International Federation of Robotics 2011). During the first few decades of this new journey, robots were not mobile. Somewhat similar to trees, these so-called "arm" manipulator robots were securely rooted to the ground. The free end of these robots typically consisted of an end-effector "hand" with which a number of mostly manufacturing-related tasks, such as welding, spray-painting, and pick-and-place operations, were performed. Life was simple, if a bit boring. However, from the end of the 1960s, this started to change.

Fiction writers had earlier imagined a variety of mobile robots such as in "I, Robot" (Asimov 1950), Otho (Hamilton 1940), and Maria (Malone 2004). Scientists and engineers also ventured to build a number of quite sophisticated machines such as the General Electric experimental "walking truck" quadruped robot by Mosher shown in Fig. 1 and the Sparko and Elektro by Westinghouse (http://en.wikipedia.org/wiki/Elektro). However, they were not considered truly autonomous in the sense we describe modern robots. Some of the major personalities who are primarily responsible for forever transforming the state of stationary existence of robots and giving them intelligent mobility are Profs. I. Kato, M. Vukobratovic, and R. McGhee, followed by Prof. M. Raibert.

Because walking robots used legs for locomotion, they immediately became the mechatronic cousins to the entire range of biological legged creatures, starting from tiny creatures to large animals. Indeed, today we have robotic versions
Walking Robots, Fig. 1 GE "walking truck" developed by Mosher

Walking Robots, Fig. 2 Adaptive suspension vehicle (ASV), Ohio State University

of spiders and cockroaches, geckoes and lizards, dogs and cheetah, and even humanoids. We have seen very large robots such as the ASV (Waldron and McGhee 1986) shown in Fig. 2 and the Dante (Bares and Wettergreen 1999), shown in Fig. 4. We have also seen single-legged robots, which even Mother Nature has not considered creating so far.

Early History

The early researchers whom we mentioned above started paving the way for walking robots. These robots walked with their legs, explored their own environments, and sometimes even ventured outside. Once these walking robots started appearing on the scene, life was never the same.

Prof. Kato pioneered walking robot research at Waseda University (Japan) through a series of remarkable biped humanoid robots, of which WL-5 is credited with genuine bipedal walking and WL-6 with displaying the first dynamic gait. At the same time, Prof. Vukobratovic was conducting research activities in exoskeleton and other areas at the Mihailo Pupin Institute (former Yugoslavia). He was instrumental in formalizing the concept of dynamic balance using the zero moment point (ZMP) concept (Sardain and Bessonnet 2004; Vukobratović and Juričić 1969), which is used to this day. In the USA, Prof. McGhee conducted path-breaking research on computer-controlled machines at the Ohio State University. He created the Ohio hexapod and later, with colleague Prof. Ken Waldron, developed the truly spectacular Adaptive Suspension Vehicle (ASV) hexapod.

Prof. Raibert started building robots in the USA, first at Carnegie Mellon University and then at Massachusetts Institute of Technology (Raibert 1989). With his colleagues, he created a series of robots, which, unlike their stationary predecessors, were characteristically full of energy. Situation permitting, they would occasionally deviate from conventional walking and running and would burst into aerial somersaults and other acrobatic motions. Prof. Raibert continues to actively shape the field of walking robots to the present day; his company Boston Dynamics (recently acquired by Google Inc.) has introduced a number of high-performance robots, such as LittleDog, BigDog, RHex, Petman, and Atlas.

The hardware, sensing, and control aspects of walking robots were steadily gaining sophistication during the 1990s. However, except for the new appreciation of walking dynamics

in the study of passive bipedal gait (McGeer 1990), there was no unexpected leap in the world of walking robots. This changed in 1996 when Honda publicly announced the humanoid robot P2, the result of their robotics project, till then unknown to the outside world. This was to be superseded by the P3 robot and then the ASIMO humanoid robot project in 2000, which became another important event in the humanoid robot history.

Characteristics of Walking Robots

Compared to other forms of land locomotion, legged walking possesses the distinct capability of locomotion using discrete footholds (Raibert 1989). Unlike wheeled mobile robots or cars, walking robots do not need a continuous prepared surface such as paved road, trail, or track in order to travel. By virtue of this single feature, a vast extent of land surface, which is not accessible to wheeled robots, opens up to walking robots. Indeed, at least in principle, walking robots are able to reach almost any location, on earth and on other planets, wherever human and other legged creatures can go.

Legged locomotion is natural to terrains where the only means of locomotion must be through the use of unstructured footholds, which can be irregularly spaced both horizontally and vertically. Due to the unique design of the leg, legged creatures can largely isolate the "payload" or the upper body from the geometric details of the terrain profile during locomotion. Both for biological creatures and for walking robots, this brings benefit in the form of significant energy savings. For walking robots this also reduces mechanical stress, vibration, and wear on the system hardware, which makes them suitable for locomotion in rough natural terrain.

In contrast, wheeled robots are typically faster, mechanically less complex, and energetically more efficient. However, these benefits must be supported by very expensive infrastructure overhead. In many places such expenditure is not practical or not even desirable.

Classification of Walking Robots

Walking robots have been built in different sizes and morphologies. These robots have ranged in sizes from small hexapods (Lewinger et al. 2005), medium-sized robots (Fig. 4), and relatively large robots such as the BigDog (Raibert et al. 2008) from Boston Dynamics and Toyota iWalk (Fig. 4) and also a few giant robots such as Dante (Bares and Wettergreen 1999) and Ambler (Fig. 4) from CMU and the ASV (Waldron and McGhee 1986) from OSU. With further miniaturization, it is conceivable that we will see even smaller walking robots in the future with unanticipated and surprising application domains. One can also imagine gigantic walking robots in potential applications in large construction sites such as in bridge, building, or ships, but we have not started seeing them just yet.

In terms of the number of legs, we have already seen monopods, Figs. 3b and 4a; bipeds, Fig. 8a–c; tripod, Fig. 4b; quadruped, Fig. 4a, b; hexapods, Figs. 4c, d and 2; octopod, Fig. 4e; and "centipede" robots with many legs, Fig. 4f.

Other than monopods, robots with odd-numbered legs are curiously absent in this list. Creatures with odd-numbered legs are also not found in nature. It is not clear if an engineering rationale is present behind this trend or the biological inspiration is simply missing for the creators of legged robots.

In addition to size and morphology, walking robots can be classified in terms of the number and types of leg joints, type of gait (e.g., walking or running), or the domain of movement. The next section is devoted to the humanoid robots, which is perhaps the most popular class of walking robots.

Humanoid Robots

Humanoid robots belong to a unique class of two-legged walking robots that has a special place in the popular psyche. These robots are the subject of special affection and fascination due to their similarity with human beings. In fact,

W
Walking Robots, Fig. 3 Early walking robots: (**a**) Waseda WL-10 (Image courtesy Atsuo Takanishi) and (**b**) one-legged robot (Image courtesy of Boston dynamics)

humanoid robots might be the original inspiration behind the entire field of robotics and perhaps also its ultimate goal. Being perpetually inspired by movies and novels, a long-standing dream of the human has been to create a mechatronic replica of themselves, the human, which will be fully general-purpose endowed with all human functionalities except perhaps the full independence of thought and action.

Humanoid robots exist in different sizes, including smaller robots such as NAO (Gouaillier et al. 2009), HOAP, and QRIO (Ishida et al. 2004) and life-sized robots such as HRP, HUBO, and ASIMO. Despite their differences, these robots bear a close resemblance to the kinematic design and proportions of a human being and share a common human-mimicking morphology. Indeed, the perceived similarity between humanoid robots and the human is so close that we routinely describe aspects of such robots using anthropomorphic terms. Terms like head, arm, hand, leg, thigh, shank, ankle, spine, gait, stumble, fall, facial expression, and even emotion are hardly ever used to describe any other man-made device. Some popular humanoid robots are shown in Fig. 9.

At current technical level, humanoid robots cannot compete in their actual utility with robots such as Roomba the vacuum cleaner, the bomb-sniffing robot, or the huge population of fully active and cost-effective welding and spray-painting robots. Yet, our fascination with humanoids remains as strong as ever, and novel applications of such robots are continuously being explored (Fig. 7). Humanoid robots are currently considered in roles of educators (Falconer 2013; Yamasaki and Nakagawa 2006), dance partners (Kosuge 2010), waiters, babysitters, companions for autistic children or for seniors (Robins et al. 2012), security, or emergency response team. Curiously, the functionality of walking is not relevant or central to many of these roles.

Dynamic Equations of Walking Robots

The dynamic equations of a walking robot can be expressed in the following form:

$$H(q)\ddot{q} + C(q,\dot{q})\dot{q} + \tau_g(q) = \Gamma + \Gamma_c + \Gamma_{\text{ext}}, \tag{1}$$

where q is the vector of the robot's generalized coordinates, which contains the world frame transformation matrix of its base link and all its joint angles. The generalized velocity vector is expressed as $\dot{q} = [v_B \quad \dot{\theta}]^T$ where v_B is the base velocity and $\dot{\theta}$ is the vector of joint velocities. Additionally, H is the joint-space inertia matrix; C is the matrix of Coriolis, centrifugal, and gyroscopic terms; and τ_g is the vector of gravity terms. Finally, $\Gamma = [0 \quad \tau]^T$ is the joint torque vector, $\Gamma_c = J_c^T f_c$ is the joint torque resulting from the contact forces f_c such as from the ground, and $\Gamma_{ext} = J_e^T f_e$ is the joint torque due to external interaction forces f_e.

The contact conditions which the robot must satisfy can be written in the form of Eq. 2. The physical constraints due to ground friction, center of pressure (CoP) condition (explained subsequently), torque limits, etc., can be expressed as in Eq. 3

$$J_c(\ddot{q}) = b(q, \dot{q}), \qquad (2)$$

$$A[\ddot{q} \quad \tau \quad f_c]^T \leq b(q, \dot{q}), \qquad (3)$$

The friction condition ensures that the robot feet do not slide on the ground, and the CoP condition corresponds to maintaining the resultant of the ground reaction force (GRF) within the perimeter of the support polygon (Sardain and Bessonnet 2004) so that toppling is prevented.

Some of the generalized coordinates of the robot, specifically those which describe the base link of the robot to the world frame, are not powered, as apparent from the joint torque vector representation $\Gamma = [0 \quad \tau]^T$, in Eq. 1. In other words, the robot is called *underactuated*. In fact, *all* walking robots are underactuated, and it is one of the central characteristics that sets these robots apart from other robots. Underactuation plays a very important role in the dynamics, motion planning, and control of walking robots (Chevallereau et al. 2005).

Balance and Stability

Even after several decades of research, balance maintenance has remained one of the most important issues of walking robots and especially of humanoid robots. Although the basic dynamics of balance are currently understood (Sardain and Bessonnet 2004; Vukobratović and Juričić 1969), robust and general controllers that can deal with discrete and nonlevel foot support as well as large, unexpected, and unknown external disturbances such as from a moving support, a slip, and a trip have not yet emerged.

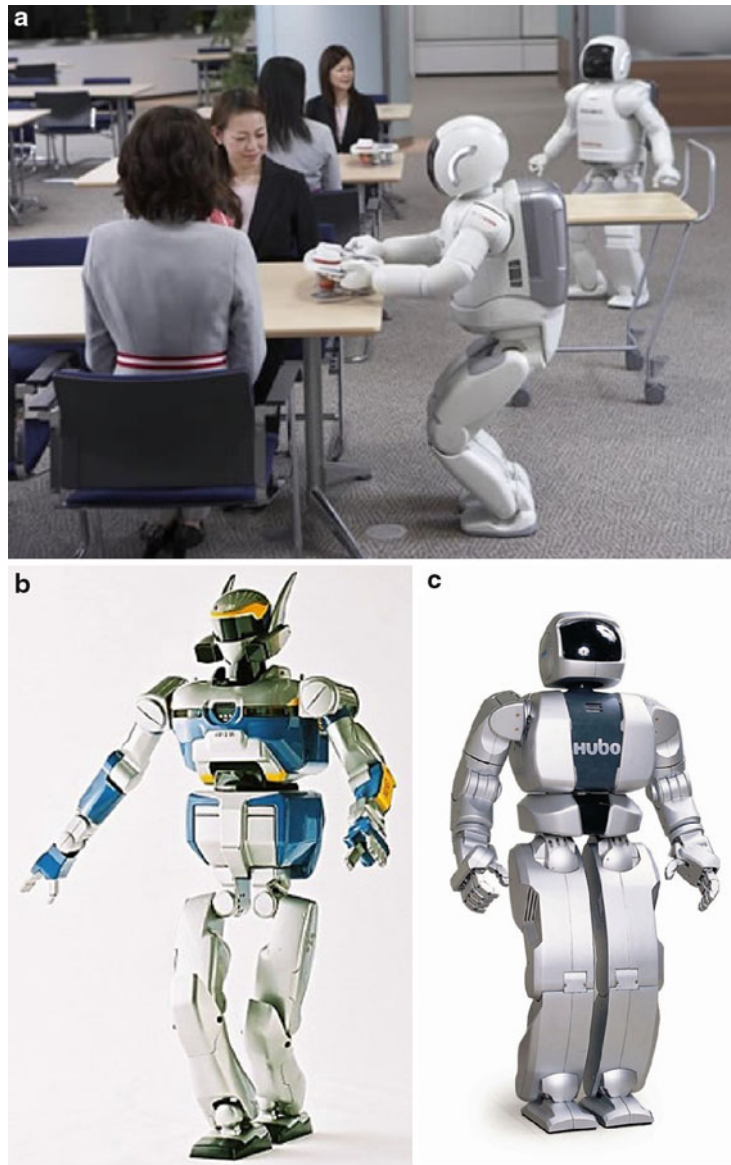
(**c**) HUBO, Korea


In comparison with the elegance and versatility of human balance, present-day humanoid robots appear quite deficient.

Balance generally refers to the ability of a walking robot to maintain a sustained gait with a reasonably upright posture without falling (Kajita and Espiau 2008). Robot gait can be static or dynamic. A robot with a static gait would continue to stay upright even if its joints were suddenly frozen. Static gait and movement under static balance are safe but are slow and lacks elegance. A dynamic gait is fluid and natural looking as it harnesses and exploits the inertial characteristics of the physical robot. However, the robot must be in motion for it to sustain an upright stature. Suddenly locking the joints may cause a fall.

The location and the nature of the resultant GRF on the support polygon of the robot have been traditionally used to interpret the dynamic state of the robot's movement. The point where the resultant GRF acts on the robot is called its

zero moment point (ZMP), and it is equivalent to the CoP for planar support. Figure 11 explains the concept of CoP.

As shown in Fig. 11, two types of interaction forces act on the foot at the foot/ground interface.

They are the normal forces f_{ni}, always directed upward (Fig. 11, left), and the frictional tangential forces f_{ti} (Fig. 11, middle). CoP, denoted by P, is the point where the resultant $R_n = \sum f_{ni}$ acts. With respect to a coordinate origin

Walking Robots, Fig. 11 Definition of center of pressure (CoP), shown for one foot of a humanoid robot. The idea can be extended to any walking robot, and in a general setting, a single footprint is replaced by the support polygon which is the convex hull of all ground contact of the robot

O, $OP = \dfrac{\sum \boldsymbol{r}_i f_{ni}}{\sum f_{ni}}$, where $\boldsymbol{r}_i$ is the vector to the point of action of force $\boldsymbol{f}_i$ and f_{ni} is the magnitude of $\boldsymbol{f}_{ni}$.

Because of the unilaterality of the foot/ground constraint $\boldsymbol{f}_{ni} \geq 0$, which implies that P must lie within the support polygon. The resultant of the tangential forces may be represented at P by a force $\boldsymbol{R}_t = \sum \boldsymbol{f}_{ti}$ and a moment $\boldsymbol{M} = \sum \boldsymbol{r}_i \times \boldsymbol{f}_{ti}$ where $\boldsymbol{r}_i$ is the vector from P to the point of application of $\sum \boldsymbol{f}_{ti}$. A basic control objective for walking robots is to maintain the CoP within the perimeter of the support polygon.

Safety

Safety is a serious concern that is paramount to any application where robots are likely to coexist in interactive human environments. The power of mobility of walking robots adds to this concern.

Out of a number of possible situations where safety is an issue, one that involves a balance loss and fall is particularly worrisome for walking robots. All walking robots, and in fact all mobile robots, are subjected to this unique "failure" mode. A fall may be caused due to unexpected or excessive external forces, unusual or unknown slipperiness, and slope or profile of the ground, causing the robot to slip, trip, or topple. Fall can also result when the balance controller is partially or fully incapacitated due to an internal failure of the robot involving its sensor or actuator.

Fall can be costly in terms of the damage to the robot and also, depending on the shape and size of the robot, can result in external damage and injury to human.

For humanoid robots, fall is a particularly serious issue (Fujiwara et al. 2002). Humanoid robots, similar to humans, have a larger ratio of CoM height to support area size, which makes them more susceptible to fall, in case of a failure. At the same time, due to their higher CoM, a fall of such robots contains generally higher kinetic energy which is able to cause higher damage and injury.

Summary

Walking robots represent an important class of autonomous machines which can find application in the general area of service robotics. The power of mobility makes these robots uniquely capable of serving in niche need areas such as plant maintenance and security, disaster response, personal companion, and so on. Humanoid walking robots have attracted strong popular fascination, and this has fueled their rapid development. At present it appears that defense-related applications are the most likely to experience practical use of walking robots.

Walking robots possess interesting and complex kinematics and dynamics. Control of such machines, especially with regard to balancing, motion planning, and reactive behavior, is a rich research area that is challenging and demands special skill-sets.

Wheeled Robots

Giuseppe Oriolo
Sapienza Università di Roma, Roma, Italy

Abstract

The use of mobile robots in service applications is steadily increasing. Most of these systems achieve locomotion using wheels. As a consequence, they are subject to differential constraints that are nonholonomic, i.e., non-integrable. This article reviews the kinematic models of wheeled robots arising from these constraints and discusses their fundamental properties and limitations from a control viewpoint. An overview of the main approaches for trajectory planning and feedback motion control is provided.

Keywords

Differential flatness; Nonholonomic constraints; Nonlinear controllability; Smooth stabilizability

Introduction

Although all robots are, by definition, capable of movement, the expression *mobile robots* is mainly used to indicate robots that can displace their own base by means of some locomotion mechanism. Most often, this consists of a set of wheels. The main advantage of mobile robots over fixed-base manipulators

is their virtually unlimited workspace. As a consequence, such robots are fundamental in service applications, which require increased capabilities of autonomous motion.

More precisely, from a mechanical viewpoint, a *wheeled robot* essentially consists of a rigid body (base) equipped with a system of wheels. This basic arrangement may be complicated, for example, by attaching to the base one or more trailers, or by mounting a manipulator on the base (mobile manipulator).

Any wheeled vehicle is subject to kinematic constraints that in general reduce its local mobility while leaving intact the possibility of reaching arbitrary configurations by appropriate maneuvers. For example, any driver knows by experience that, while it is impossible to move instantaneously a car in the direction orthogonal to its heading, it is still possible to park it anywhere, at least in the absence of obstacles. This peculiar feature makes wheeled mobile robots very challenging from the control viewpoint, and in fact, some recent developments in nonlinear control were triggered by the study of these systems.

Here, we will consider only mobile robots that are equipped with conventional wheels, either orientable or fixed (as the front or rear wheels of a car, respectively). Omnidirectional mobile robots realized using, e.g., Mecanum wheels, are not covered in this article. Indeed, the local mobility of these vehicles is unrestricted, and therefore no special control treatment is necessary.

The most popular wheel arrangement for mobile robots is the *differential drive*, in which two fixed wheels whose axes of rotation coincide are controlled by separate actuators (see Fig. 1). One or more passive (caster) wheels are usually added for statical balance. This wheeled robot is the most agile, in that it can rotate on the spot by applying equal and opposite angular speeds to the wheels. A kinematically equivalent arrangement is the *synchro drive*, in which three orientable wheels are synchronously driven by two motors through mechanical coupling; the first motor provides traction, whereas the second controls the common orientation of the wheels.

Other possible wheel arrangements are those of a tricycle (one steering and two fixed wheels)

Wheeled Robots, Fig. 1 The Pioneer by Adept is a popular differential-drive platform

**Wheeled Robots, Fig. 2** Generalized coordinates for a single wheel

and of a car (two steering and two fixed wheels). Vehicles of this type are however less common in robotics, due partly to their reduced maneuverability (they have a nonzero turning radius) and partly to their increased mechanical complexity. For example, both these vehicles require a specific device (differential) for distributing traction torque to the driving wheels.

Modeling

The starting point for modeling wheeled mobile robots is the single wheel. This may be represented as an upright disk rolling on the ground. Its configuration is described by three generalized coordinates: the Cartesian coordinates (x, y) of the contact point with the ground, measured in a fixed reference frame, and the orientation θ of the disk plane with respect to the x axis (see Fig. 2). The configuration vector is therefore $q = (x \ \ y \ \ \theta)^T$. The *pure rolling* constraint is expressed as

$$\begin{pmatrix} \sin \theta & -\cos \theta \end{pmatrix} \begin{pmatrix} \dot{x} \\ \dot{y} \end{pmatrix} = 0 \qquad (1)$$

and entails that, in the absence of slipping, the velocity of the contact point has a zero component in the direction orthogonal to the wheel plane. The angular speed of the wheel around the vertical axis is instead unconstrained.

The kinematic constraint (1) is *nonholonomic*, i.e., it cannot be integrated to a geometric constraint; this may be easily shown using Frobenius theorem, a well-known differential geometry result on integrability of differential forms. An important consequence of this fact is that constraint (1) implies no loss of accessibility in the configuration space of the wheel.

In a single-body vehicle equipped with multiple wheels, the n-dimensional configuration vector q consists of the Cartesian coordinates of a representative point on the robot, the orientation of all independently orientable wheels, plus the orientation of the body if there are fixed wheels. By writing one pure rolling constraint like (1) for each independent wheel, orientable or fixed, and expressing it in the chosen generalized coordinates, one obtains a set of k constraints in the form

$$A^T(q)\dot{q} = 0. \qquad (2)$$

Kinematic constraints of this form (i.e., linear in the generalized velocities) are called *Pfaffian*. In wheeled mobile robots, Pfaffian constraints are in general completely nonholonomic.

The k Pfaffian constraints (2) reduce the number of degrees of freedom (i.e., independent instantaneous motions) of the robot to $m = n - k$. In particular, at each configuration q, the generalized velocities must belong to the m-dimensional null space of matrix $A^T(q)$:

$$\dot{q} = \sum_{j=1}^{m} g_j(q)u_j = G(q)u, \qquad (3)$$

where vectors $g_1(q), \ldots, g_m(q)$ are a basis of $\mathcal{N}(A^T(q))$ and $u = (u_1 \ \ldots \ u_m)^T$ is a coefficient

W

vector. Kinematically admissible trajectories are the solutions of (3), which is called *kinematic model* of the wheeled mobile robot. This model can be seen as a nonlinear dynamic system, with q as state and u as input. In particular, system (3) is driftless and has more state variables than control inputs.

For example, consider the *unicycle*, a rather ideal mobile robot equipped with a single, orientable wheel. The generalized coordinates for this robot are $q = (x\, y\, \theta)^T$, the same as the single wheel, and the vehicle is subject to the rolling constraint (1). One possible kinematic model for the unicycle is then

$$\begin{pmatrix} \dot{x} \\ \dot{y} \\ \dot{\theta} \end{pmatrix} = \begin{pmatrix} \cos\theta \\ \sin\theta \\ 0 \end{pmatrix} v + \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix} \omega, \qquad (4)$$

where $v = \sqrt{\dot{x}^2 + \dot{y}^2}$ and $\omega = \dot{\theta}$ represent, respectively, the driving and steering velocity of the wheel. Both the differential-drive and the synchro-drive robots are kinematically equivalent to the unicycle, i.e., their kinematic model can be put in the form (3) by properly defining q and u.

Similar to what is done for robot manipulators, the dynamic models of wheeled mobile robots may be derived following the Euler-Lagrange method. The main difference is the presence of the nonholonomic Pfaffian constraints, which give rise to reaction forces expressed via Lagrange multipliers (Neimark and Fufaev 1972).

Structural Properties

The nonholonomic nature of wheeled mobile robots has precise consequences in terms of structural properties of the kinematic model (3).

The first, and most important, is that in spite of the reduced number of degrees of freedom, a wheeled robot is *controllable* in its configuration space; i.e., given two arbitrary configurations, there always exists a kinematically admissible trajectory (with the associated velocity inputs) that transfers the robot from one to the other
Wheeled Robots, Fig. 3 In spite of its restricted local mobility, a nonholonomic wheeled robot can reach any point in its configuration space

(Fig. 3). Since the kinematic model (3) is driftless, a well-known result (Chow theorem) implies that it is controllable if and only if the accessibility rank condition holds:

$$\dim \bar{\Delta} = n, \qquad (5)$$

where $\bar{\Delta}$ denotes the involutive closure of distribution $\Delta = \{g_1, \ldots, g_m\}$ under the Lie bracket operation. In turn, this is guaranteed to be true in view of the nonholonomy of constraints (2). For example, since the Lie bracket of the two input vector fields in (4) is always linearly independent from them, the kinematic model of the unicycle is controllable.

However, the controllability of wheeled mobile robots is intrinsically nonlinear. In fact, the linear approximation of (3) at any configuration clearly results to be uncontrollable due to the reduced number of inputs. In practice, this means that no linear feedback can stabilize the system at a given configuration. The situation is actually worse: for nonholonomic robots, there exists no continuous time-invariant feedback law that provides point stabilization. This negative result can be established on the basis of a celebrated result on smooth stabilizability of control systems due to Brockett (1983). Note that the result does

not apply to time-varying stabilizing controllers, which may thus be continuous in q.

Another related drawback of wheeled mobile robots is that in general, they do not admit *universal* controllers, i.e., feedback control laws that can asymptotically stabilize arbitrary state trajectories, either persistent or not (Lizárraga 2004). This means that, in principle, tracking and regulation problems in wheeled robots should be addressed using separate approaches.

All the above limitations of nonholonomic systems are established with reference to the kinematic model, but of course, they are passed on to dynamic models. Altogether, they contribute to making the control problem for wheeled mobile robots much more difficult than, for example, for robotic manipulators, which are linearly controllable, smoothly stabilizable and admit universal controllers.

Trajectory Planning

Trajectory planning for wheeled robots is a nontrivial problem, because not all trajectories are feasible – once again, a consequence of nonholonomy. This leads to the necessity of maneuvering, i.e., performing certain specific movements, in order to execute transfer motions.

Most kinematic models of wheeled mobile robots exhibit a property known as *differential flatness* (Fliess et al. 1995): namely, there exists a set of outputs z, called *flat* outputs, such that the state q and the control inputs u can be expressed algebraically as a function of z and its time derivatives up to a certain order σ:

$$q = \varphi\left(z, \dot{z}, \ddot{z}, \ldots, z^{(\sigma)}\right) \qquad (6)$$

$$u = \gamma\left(z, \dot{z}, \ddot{z}, \ldots, z^{(\sigma)}\right). \qquad (7)$$

As a consequence, once an output trajectory $z(t)$ is specified, the associated state trajectory $q(t)$ and control history $u(t)$ are uniquely determined. For example, the unicycle admits $z = (x \ \ y)^T$ as flat outputs. In fact, once a Cartesian trajectory is assigned for the contact point with the ground, the wheel orientation $\theta(t)$ is constrained to be tangent to the trajectory; the associated control input v and ω are then uniquely and algebraically computable from $q(t)$.

Differential flatness is particularly useful for planning. For example, assume that we want to transfer a wheeled mobile robot from an initial configuration q_i to a final configuration q_f. One then computes the corresponding values z_i and z_f of the flat outputs, plus the appropriate boundary conditions, and uses any interpolation scheme (e.g., polynomial interpolation) to plan the trajectory of z. The evolution of the generalized coordinates q, together with the associated control inputs u, can then be computed algebraically from (6–7). The resulting configuration space trajectory will automatically satisfy the nonholonomic constraints (2).

Another approach to nonholonomic trajectory planning is based on the possibility of putting the equations of most wheeled robots into a canonical format known as a 2-input *chained form*

$$
\begin{aligned}
\dot{z}_1 &= w_1 \\
\dot{z}_2 &= w_2 \\
\dot{z}_3 &= z_2 w_1 \qquad\qquad (8) \\
&\ \ \vdots \\
\dot{z}_n &= z_{n-1} w_1
\end{aligned}
$$

by means of a feedback transformation, i.e., a change of coordinates $z = \alpha(q)$ coupled with an input transformation $w = \beta(q)u$. In particular, this is always possible with kinematic models (3) for which $n \leq 4$ and $m = 2$ (e.g., unicycle or car-like robots). Once the system is cast in the form (8), one may use sinusoidal open-loop controls at integrally related frequencies to drive all variables sequentially to their final values (Murray and Sastry 1993). This approach is particularly interesting from a theoretical viewpoint because such control maneuvers achieve motion in the direction of the Lie brackets of the input vector fields.

Note that differential flatness and chained-form transformability are equivalent properties for 2-input nonholonomic mobile robots.

W

Feedback Control

The motion control problem for wheeled mobile robots is generally formulated with reference to the kinematic model (3). For example, in the case of the unicycle (4), this means that the control inputs are directly v and ω, the driving and steering velocities. There are essentially two reasons for taking this simplifying assumption.

First, the kinematic model (3) fully captures the essential nonlinearity of single-body wheeled robots, which stems from their nonholonomic nature. This is another fundamental difference with respect to the case of robotic manipulators, in which the main source of nonlinearity is the inertial coupling among multiple bodies. Second, in mobile robots it is typically not possible to command directly the wheel torques, because there are low-level wheel control loops integrated in the hardware or software architecture. Any such loop accepts as input a reference value for the wheel angular speed, which is then reproduced as accurately as possible by standard regulation actions (e.g., PID controllers). In this situation, the actual inputs available for high-level control are precisely these reference velocities.

Two basic control problems can be considered:
- *Trajectory tracking*: the robot must asymptotically track a desired Cartesian trajectory $(x_d(t), y_d(t))$.
- *Point stabilization*: the robot must asymptotically reach a desired configuration q_d.

From a practical point of view, the most relevant of these problems is certainly the first. This is because mobile robots must be able to operate in unstructured workspaces that invariably contain obstacles. Clearly, forcing the robot to move along (or close to) a trajectory planned in advance reduces considerably the risk of collisions. The point stabilization problem, however, is more difficult and therefore particularly interesting from a scientific perspective. In a certain sense, the relative difficulty of the two problems is reminiscent of human car driving: learning to drive a car along a road is relatively easy, whereas parking poses a greater challenge.

Trajectory Tracking

Several methods are available to drive a wheeled mobile robot in feedback along a desired trajectory. A straightforward possibility is to compute first the linear approximation of the system along the desired trajectory (which, unlike the approximation at a configuration, results to be controllable) and then stabilize it using linear feedback. Only local convergence, however, can be guaranteed with this approach. For the kinematic model of the unicycle, global asymptotic stability may be achieved by suitably morphing the linear control law into a nonlinear one (Canudas de Wit et al. 1993).

In robotics, a popular approach for trajectory tracking is input–output linearization via static feedback. In the case of a unicycle, consider as output the Cartesian coordinates of a point B located ahead of the wheel, at a distance b from the contact point with the ground. The linear mapping between the time derivatives of these coordinates and the velocity control inputs turns out to be invertible provided that b is nonzero; under this assumption, it is therefore possible to perform an input transformation via feedback that converts the unicycle to a parallel of two simple integrators, which can be globally stabilized with a simple proportional controller (plus feedforward). This simple approach works reasonably well. However, if one tries to improve tracking accuracy by reducing b (so as to bring B close to the ground contact point), the control effort quickly increases.

Trajectory tracking with $b = 0$ (i.e., for the actual contact point on the ground) can be achieved using dynamic feedback linearization (Oriolo et al. 2002). In particular, this method provides a one-dimensional dynamic compensator that transforms the unicycle into a parallel of two double integrators, which is then globally stabilized with a proportional-derivative controller (plus feedforward). In contrast to static feedback linearization, no residual zero dynamics is present in the transformed system. However, the dynamic compensator has a singularity when the unicycle driving velocity is zero. This is expected, because otherwise the tracking

controller would represent a universal controller. Note that dynamic feedback linearizability using the x, y outputs is related to them being flat – the two properties are equivalent.

Point Stabilization

The impossibility of stabilizing a nonholonomic mobile robot using continuous pure-state feedback has generated two main directions of research to solve the problem:

- *Discontinuous* feedback, i.e., time-invariant control laws $u = \gamma(q)$, where γ is discontinuous precisely at the configuration that one seeks to stabilize.
- *Time-varying* feedback, in the form $u = \gamma(q, t)$ where γ may or may not be continuous at the desired configuration.

For the unicycle, a well-known stabilizing controller belonging to the first category was designed by Aicardi et al. (1995) by formulating the problem in polar coordinates centered at the goal and then using a Lyapunov-like analysis to establish asymptotic convergence. The controller, once rewritten in original coordinates, turns out to be discontinuous at the goal (not surprisingly). Although this rules out proper stability in the sense of Lyapunov, this controller is effective in that it produces rather natural approach trajectories to the goal.

Continuous time-varying stabilizers in the sense of Lyapunov exist (Samson 1993) but have mainly theoretical interest due to their provably slow (polynomial) rate of convergence; this is a direct consequence of the fact that the linear approximation of the system is not controllable. A more effective approach is to give up (Lipschitz-) continuity at the desired configuration. As shown by M'Closkey and Murray (1997) and Morin and Samson (2000), this allows to design control laws that guarantee a modified form of exponential convergence to the goal.

Most of the aforementioned control designs – both for trajectory tracking and point stabilization – were first developed with reference to the unicycle robot but can be carried out on chained forms, thereby providing an effective extension to other kinematic models, e.g., the car-like robot.

Summary and Future Directions

Wheeled mobile robots are increasingly present in applications. Over the last two decades, significant results have been reached in terms of modeling, planning and control of these systems, and the field is now considered to be well established, at least from an application point of view. Nevertheless, a number of research directions are still open, including the following:

- *Planning and control for non-flat systems*: Relatively harmless wheeled robots (such as a unicycle towing more than one off-hooked trailer) are not flat.
- *Robustness*: The performance of controllers in the presence of disturbances and model perturbations has not received sufficient attention so far.
- *Localization*: Feedback control requires accurate measurements of the configuration variables, which in mobile robots cannot be reliably reconstructed from onboard sensors (odometric data). Integration of exteroceptive sensing is essential to this end.
- *Vision-based control*: As an alternative to localization-based methods, the feedback loop may be closed directly in the image plane, with significant advantages in terms of simplicity and robustness.
- *Multi-robot systems*: The problem is to control the motion of multiple mobile robots in order to perform a cooperative motion task, e.g., formation control.

Recommended Reading

For background material on nonlinear controllability, including the necessary concepts of differential geometry, see Sastry (2005). General introductions to mobile robots can be found in Siegwart and Nourbakhsh (2004), Choset et al. (2005), Morin and Samson (2008), and Siciliano et al. (2009). A classification of wheeled mobile robots based on the number, placement, and type of wheels was proposed by Bastin et al. (1996). A detailed extension of some of the planning and control techniques reviewed in this article to the case of car-like kinematics is given in De Luca et al. (1998). A framework for the stabilization of non-flat nonholonomic robots was presented by Oriolo and Vendittelli (2005). Recent work aimed at designing practical universal controllers was carried out by Morin and Samson (2009).
